FURTHER OBSERVATIONS ON INJURIES OF THE NECK OF THE FEMUR IN EARLY LIFE;

WITH REFERENCE TO THE DISTINCTION BETWEEN FRACTURE OF THE NECK AND EPIPHYSEAL DISJUNCTION AS INFLUENCING POSITIVE TREATMENT.*

By ROYAL WHITMAN, M.D.,

NEW YORK.

In 1890 I presented at a meeting of this Section a case of fracture of the neck of the femur in a child, and in succeeding years reported other cases as they came under my observation. Later, when the *x*-ray became available for diagnosis, injuries of this character could be easily demonstrated and their comparative frequency began to attract attention.

In 1898, Sprengel, who had had under observation for a year or more two youths, aged respectively seventeen and eighteen, suffering from increasing pain and disability, supposed to be caused by disease of the hip joint, performed on each the operation of excision, the specimens illustrating epiphyseal fracture. (*Archiv f. klin. Chir.*, Band 47, S. 805.) On such evidence, so positive and yet misleading, it was generally assumed that practically all fractures at the hip in early life were of this character. For example, Hoffa in 1903 (*Zeits. f. Ortho. Chir.*) analyzed 84 cases collected from literature. Of these he concluded that 80 were epiphyseal fractures and that but 4, all of which had been reported by myself, were fracture of the neck.

The distinction between a fracture at the epiphyseal junction and another, a fraction of an inch removed from it, is not always clear to one who is inexperienced in the differential diagnosis of this class of injuries; moreover, the impression has long prevailed that the younger the child, in other words, the more pronounced the distinction between the developing and the finished bone, the greater the likelihood of epiphyseal disjunction. It may be questioned, therefore, if the name under which these cases are reported, has, in most instances, any particular significance.

In very early childhood the greater part of the upper extremity of the femur is cartilaginous, the centers of ossification for the head and neck being widely separated, as is well shown in *x*-ray pictures. At this period and during the first ten years of life at least, epiphyseal separation is unusual because the junction is protected by a firm enclosing covering of cartilage, reinforced by periosteal tissue. This comparative strength is illustrated by the resistance offered to forced and persistently repeated abduction in the reduction of congenital dislocation of the hip, the movement that is experimentally the most effective in producing disjunction at this joint. In adolescence, however, the junction becomes relatively weak, for while there is an approximation to the adult shape and structure, there yet remains a thin segment of cartilage with newly forming and therefore vulnerable bone on the diaphyseal side. It is through this partly consolidated tissue that complete or partial separation occurs, also the form of epiphyseal coxa vara in which the head is displaced downward and backward of the neck retains its normal angle; a form which, when unilateral, is in most instances induced by injury, in other words, a fracture rather than a developmental deformity.

As traumatic epiphyseal separation must be classed as fracture of the neck of the femur, an injury once ignored, but now generally recognized, it may be asked why the exact location of the lesion is of particular interest.

If one were content with the accepted methods of treatment of this fracture, in the light of the results attained, or if there were no remote penalties for uncorrected deformity in early life, or if one considers excision of the head of the femur—"Sprengel's operation"—as a remedy and not a mutilation, there would be no practical advantage in correct diagnosis. Fortunately, however, a higher standard must be eventually recognized and I shall again point out the distinction between the two classes of injury with reference to its influence on treatment conducted for the purpose of restoring the function of the injured part.

As regards history, it may be stated that an injury to the hip in a healthy subject resulting in immediate disability and presenting the physical signs of fracture, whether in childhood or adolescence, is far more likely to be a fracture of the neck than at the epiphyseal junction. In the first ten years of life the injury is almost certainly of the neck. In adolescence it is probably at this point. If, on the other hand, the subject is an adolescent, particularly of the weak, rapidly growing or over-weighted type, if the symptoms were induced by comparatively slight injury; if the disability was not complete, but slowly progressive, the probability is that the lesion is an incomplete epiphyseal fracture. For if the separation is immediate and complete the injury is usually more severe, involving leverage of the limb upon the head, and the disability is correspondingly greater

In the cases of fracture of the neck, after the primary pain and weakness have lessened, the patient begins to walk about and later is brought for treatment because of a persistent limp, usually accompanied by slight discomfort. The physical signs, aside from the limp, are an inch or less of shortening, prominence and elevation of the trochanter and

*Read in part before the Orthopedic Section of the New York Academy of Medicine.

slight outward rotation of the limb. Motion is practically free except in abduction, which is restricted in accordance with the degree of depression of the neck.

These symptoms, called characteristic, are, it may be noted, those of the stage of repair, which, persisting after recovery from what was thought to be a contusion, are mistaken for those of hip disease. As repair in these cases has been unaided by treatment, it must be assumed that the fracture is usually incomplete. In other instances it may be complete, and non-union may follow treatment by conventional methods, as in four cases that have come under my observation, in three of which operative intervention permitted direct inspection.

The results after non-treatment, compared with those of the adult class, from the accepted standpoint would be considered extremely good, but as I have on other occasions pointed out, as the lessened angle induces adduction, and as the strain is proportionately increased, the deformity and the consequent disability are, as in other forms of coxa vara, usually progressive. Treatment, therefore, if effective, must restore the normal contour.

If one has an opportunity to treat the patient before consolidation is advanced, the limb should, under traction and by carefully applied force, be placed and fixed in complete abduction for the purpose of reducing the deformity, in the manner that I have so often described. If, however, as in most instances, repair has taken place, a sufficient wedge of bone should be removed from the base of the trochanter to restore the angle of the neck and thus the range of abduction which is dependent upon it.

The characteristic cases of epiphyseal fracture are, in adolescents: The injury is comparatively slight, so slight, it may be, as to pass unnoticed. The disability is not immediate nor complete, but the symptoms become progressively more disabling during the time that in fracture is the period of repair. Motion becomes more limited, until, in many instances, there is practical fixation at the joint. The reason is evident. In fracture of the neck of the femur the joint is not directly involved; in epiphyseal fracture it is, thus movements are restricted by the irregularities of the opposing surfaces and by the muscular spasm that is symptomatic of all joint injuries and diseases. In fracture of the neck the history and the physical signs point directly to injury and consequent deformity, whereas in epiphyseal fracture the superficial indications are often those of disease.

The final results of untreated cases of fracture of the neck are distortion and apparent shortening of the limb, but comparative freedom of motion in directions not opposed by the deformity. In epiphyseal displacement there is, in addition, great limitation of motion or partial anchylosis resulting from disorganization of the joint, with a certain degree of shortening due to loss of growth.

In rare instances the epiphyseal separation may be complete so that a disengagement and replacement of the fragments by manipulation may be possible, but in most cases, at least at the time when the opportunity for intelligent treatment is offered, the fragments are firmly adherent to one another and reposition is impossible without open operation. This operation is indicated therefore in all characteristic cases for the purpose of relieving pain, checking the progression of the deformity and restoring function. As this procedure is almost never required for fracture of the neck, the importance of the distinction between the two forms of injury which I was, I believe, the first to make and the first to act upon, is evident.

Partial displacement to the degree to interfere markedly with the movement of the joint, and in rare instances complete separation, are the cases that one usually has an opportunity to treat.

Undoubtedly there are others in which there is an injury and even slight separation at the epiphyseal junction, in which the character of the lesion cannot be demonstrated. These may recover spontaneously, or they may be treated for disease and pass as remarkable cures, or in the absence of protection the displacement slowly increases and finally the case is classed as epiphyseal coxa vara, the essential distinction being that in this type the slowly increasing deformity is accompanied by a certain degree of repair and functional adaptation to the new conditions.

If the fracture might be detected in these early cases, protective treatment would probably assure repair, but such diagnostic ability can hardly be looked for at the present time when the characteristic cases are overlooked or treated for hip disease.

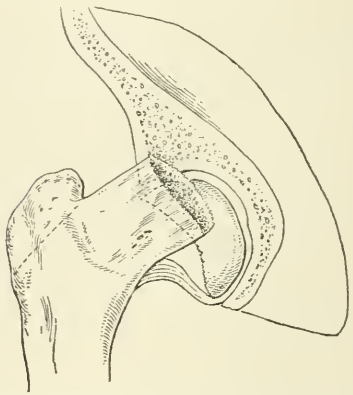

Fig. 1.—The ordinary type of epiphyseal fracture in which the neck presents in front and above the head, illustrating the disorganization of the joint.

Thus far the *x*-ray has not been mentioned. Usually by its means one may demonstrate cases of fracture of the neck or of complete epiphyseal disjunction, but in many cases of the incomplete type, the shadow is ill defined and the blurred outline may be thought to confirm a diagnosis of disease.

I shall now present briefly a number of illustrative cases of fracture of the neck of the femur, particularly of the epiphyseal type, from which the foregoing conclusions have been drawn.

Case I. A girl, 15 years of age, without appreciable cause, began to limp and to complain of stiffness referred to the right thigh. These symptoms increased and eight weeks later, on November 23, 1903, she was admitted to the Hospital for Ruptured and Crippled. She was of the overgrown type, the disability was complete, the limb being fixed in extension and outward rotation by muscular spasm. On opening the joint the head of the femur was found to be displaced slightly downward and backward, exposing the sharp angular anterior border of the neck. As the fragments were firmly adherent this projection was removed and the wound was closed. At the end of three months she

began to use the limb and when last seen, several months later, function appeared to be perfect, with the exception of some limitation of flexion.

Case II. A tall, strong boy, 15 years of age, was thrown down and dragged for half a block by a street car. After the accident he suffered from stiffness and discomfort about the right hip, but continued to work for two months when the symptoms increased to the point of disability and he was admitted to the Hospital for Ruptured and Crippled on December 28, 1903. The limb was fixed in an attitude of extension and outward rotation, a resistant swelling was apparent on the anterior aspect of the joint, there was half an inch of shortening. On opening the joint, the swelling was the extremity of the neck of the femur. From this a thin section of bone was removed to permit a chisel to be passed between it and the head of the bone, then by leverage and by rotation of the limb the fragments were adjusted. A perfect functional cure followed. The patient is now a fireman on a locomotive.

Case III. A well developed girl, 14 years of age, was admitted to the Hospital for Ruptured and Crippled on July 27, 1907, for the treatment of hip disease. About six weeks before, without known cause, she began to limp and to complain of stiffness and discomfort about the left hip. Four weeks later she fell on the stairs, since then she had been unable to walk. There was much pain when the limb was moved, but none when at rest. The left limb was fully extended and rotated outward, motion was painful and was restrained by muscular spasm. The shortening was less than half an inch. The diagnosis of epiphyseal fracture was made and the joint was opened. The head of the bone was completely concealed by the projecting extremity of the neck. A thin section having been removed the limb could be rotated inward and perfect apposition attained. The plaster spica was retained for eight weeks and crutches were used for several weeks longer. There is at present perfect functional cure.

Case IV. A very fat girl, 12 years of age, was brought to the Hospital for Ruptured and Crippled on March 25, 1907. About four weeks before she had slipped on a carpet and had fallen on the left hip. She then limped and complained of stiffness and discomfort. On March 18 another fall caused complete disability. In this case the outward rotation of the limb was so extreme that the outer border of the foot was parallel to the table. The limb was slightly adducted and flexed to an angle of 150°. There was practically no motion. The operation was somewhat difficult in that the joint was about three inches from the surface and in that a wide fragment of cartilage was adherent to the exposed neck, giving the impression of a shattered head. A somewhat large and wedge-shaped section of the bone was removed before satisfactory apposition could be assured. At the last examination, several months ago, a slight limp persisted and the range of abduction was limited to about one-half of the normal.

Case V. A rather slender girl, 12 years of age, was admitted to the Hospital for Ruptured and Crippled on December 25, 1907, for the treatment of hip disease. Nine weeks before, without known cause, she began to complain of pain and stiffness about the left hip. These symptoms increased, and one week later she was obliged to remain for a time in bed, after which the pain subsided, to reappear on walking. The physical examination of this patient differed somewhat from that of the others in that the limb was flexed, abducted and rotated outward. Motion was painful and almost entirely restrained by muscular spasm, a typical picture of hip disease. There was, however, three-quarters of an inch of shortening. The *x*-ray negative showed what might have been interpreted as destructive disease, but which was in reality displacement of the head of the bone. The usual operation was performed. In this case a fragment of cartilage was adherent to the neck. Reduction was easily accomplished in the manner described. At the present time there is no limp or disability, and a perfect functional cure may be predicted.

Case VI. A large girl, 13 years of age, was admitted to the Hospital for Ruptured and Crippled

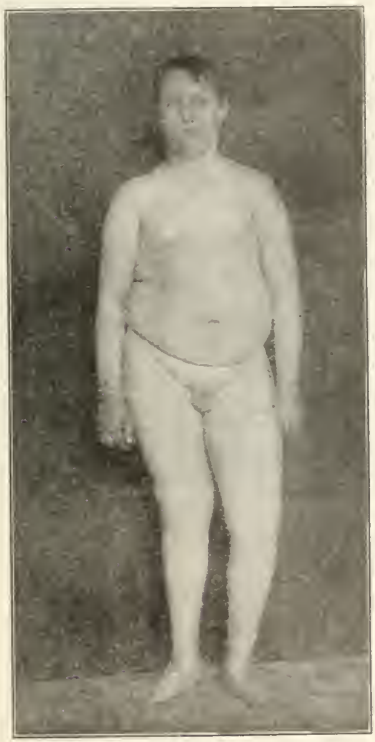

Fig. 2.—Case VII. The overgrown type, illustrating the predisposition to deformity.

on December 6, 1906. One month before she had fallen down a flight of stairs injuring the left hip. She was unable to walk and was taken to a hospital where she was treated for contusion, but as she continued to limp she was transferred to the Hospital for Ruptured and Crippled. In this case epiphyseal injury was thought to be probable, although there was no shortening. Repeated attempts failed to produce a satisfactory *x*-ray picture. My term of service coming to an end, I did not again see the patient for a year, when she was again admitted because of the persistent pain, limp and a restriction of motion to a range of about 20°. At this time shortening of half an inch was evident. The operation was performed on December 3, 1907, and a typical epiphyseal fracture was found. In this

case it seemed necessary to remove a wedge-shaped segment from the extremity of the neck in order to permit reposition by inward rotation. This patient has returned to the institution from which she came. When last examined the attitude was normal. There was no pain, and the range of motion under massage and voluntary exercises was increasing.

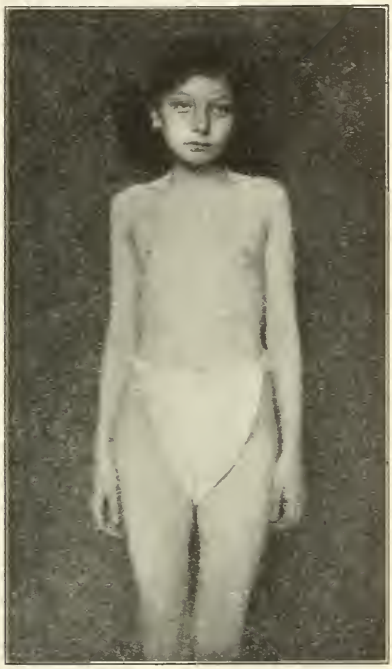

FIG. 3.—Case IX. Complete epiphyseal separation as shown in Fig. 4. The only distortion shown in this photograph, taken before operation, is the outward rotation of the left limb.

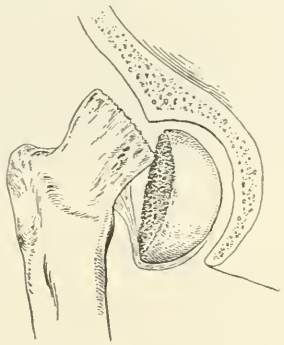

FIG. 4.—Drawing from the *x*-ray picture of Case IX, showing complete separation of the fragments which permitted reposition by means of traction and abduction.

CASE VII. This patient, a very fat adolescent boy of 14 years, was admitted to the Hospital for Ruptured and Crippled on April 1, 1908. On December 17, 1907, he had fallen three or four steps injuring the right hip. Since then he had suffered from increasing stiffness, weakness and pain in the limb so that eventually he was obliged to use crutches. The limb was flexed about 20°, adducted, rotated outward and practically fixed by muscular spasm. On April 6 the joint was opened. In this case the entire anterior surface of the neck presented a shining white appearance as if covered with cartilage. On removal of a wedge of bone at the epiphyseal junction the head of the bone came into view and the parts were apposed by rotating the limb inward. The wound was closed and a plaster spica applied to hold the limb in abduction and inward rotation. The patient was discharged in June, and function has steadily improved. The peculiar smooth cartilaginous appearance of the neck differing so entirely from all other cases in which the impression was of a rough red surface from which the periosteum had been torn away, suggested that in this case there had been a gradual displacement induced or exaggerated by injury, a type of epiphyseal coxa vara. The accompanying photograph illustrates the type of case in which predisposition to deformity, whether induced by injury or by occupation, evidently exists.

CASE VIII. A large boy, 15 years of age, was admitted to the Hospital for Ruptured and Crippled in April, 1908. Fourteen months before he had slipped and fallen on the ice, injuring the left hip. Since then he had limped but had continued to work as a grocer's boy until February, when he again strained the limb and became practically disabled. He was then, because of pain and inability to walk, admitted to a hospital where an examination was made under an anesthetic. Four weeks later he was discharged. He presented the usual signs of epiphyseal fracture, namely, extreme outward rotation of the limb, which was practically fixed in the extended attitude by muscular spasm, with but a fraction of an inch of shortening. The operation was performed on April 11, 1908. On opening the joint the extremity of the neck presented, apparently completely separated from the head. A section of bone about a quarter of an inch in width was removed which permitted the insertion of a chisel by which the fragments were pried apart sufficiently to permit apposition by inward rotation of the limb. The wound was closed and a plaster spica applied which was removed eight weeks later. The patient was then discharged on crutches.

CASE IX. This case illustrates the less common type of complete separation. A girl, 14 years of age, was admitted to the Hospital for Ruptured and Crippled on January 11, 1906. Three weeks before she had been thrown down on the sidewalk, striking the left hip. The injury caused immediate disability and much pain on movement, symptoms supposed to be the effect of the disease. In this case the limb was practically extended and fixed in outward rotation and adducted. There was crepitus on motion. An *x*-ray picture showed complete epiphyseal separation. Under anesthesia the deformity was reduced and the limb was fixed in complete abduction. The child was soon after removed from the Hospital and I have not seen her since. She was, however, examined recently by Dr. Preston, House Surgeon at the Hospital, who reports a satisfactory result. There is but very slight limp, no discomfort, three-quarters of an inch of shortening. Motion from complete extension to 135° of flexion, abduction limited to about one-half.

CASE X. A well-developed girl, 13 years of age, was brought to the Hospital on May 28, 1908, for pain and stiffness referred to the left hip. These symptoms were first noticed in November, 1907, and

on further questioning it appeared that they had followed a fall on the ice. There was a very noticeable limp, the limb was slightly flexed, adducted,

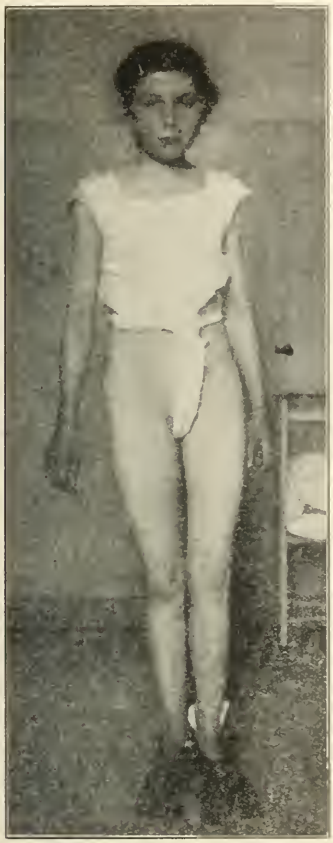

Fig. 5.—Case X. Incomplete epiphyseal fracture. See Fig. 6

Fig. 6.—Direct downward displacement as in Case X, illustrating the limitation of abduction by contact of the neck and the upper border of the acetabulum.

and rotated outward. The trochanter was somewhat prominent and elevated. The limb was one-half an inch shorter than its fellow. The joint was sensitive to pressure, motion was much restricted by muscular spasm and was accompanied by discomfort. The patient was admitted to the hospital and the operation was performed on June 17. The fracture differed somewhat from the ordinary type, in that the neck was displaced upward and but slightly forward, its lower third being united to the head which was exposed by the incision. The fragments, having been separated by a chisel, were brought into proper relation by abduction and flexion of the limb. In this instance the efficacy of the method of reducing the deformity following fracture of the neck of the femur, whether impacted or not, which I have advocated, was clearly demonstrated. By traction the upward displacement was sufficiently reduced so that as the limb was abducted, the extremity of the neck slipped beneath the rim of the acetabulum. Further abduction against this fulcrum, the head being fixed by the tense capsule beneath, forced its extremity directly downward into contact with the fractured surface of the head, and when fixed in this attitude by the plaster spica there could be no possibility of redisplacement. In this case the original spica bandage is still in place.

Case XI. This case, which was treated before the importance of immediate correction of deformity was appreciated, is introduced to illustrate what may be termed a final result of injuries of this class. The patient, a boy 16 years of age, came to the Hospital on October 10, 1899, walking with the aid of a crutch. Three weeks before, his left hip had been injured by a violent abduction of the thigh in a game of football. This was a typical case of partial epiphyseal separation, as demonstrated by an x-ray picture. There was one inch of shortening. A light plaster bandage was applied together with a traction hip splint to remove weight. This treatment relieved the symptom, and the patient, having been observed from time to time, served to illustrate the futility of so-called conservative treatment. Three years later there was an actual shortening of two inches, an apparent shortening of three inches, and at the end of seven years, an examination showed no change except an increase in the actual shortening.

The eleven cases described present fairly the characteristics of the epiphyseal type of fracture of the neck of the femur. Seven of the patients were females, and four were males, all were adolescents. In two cases the violence was relatively severe, in the others slight, so slight in several cases as not to be mentioned in the history. The contrast in this regard with those of fracture of the neck of the femur is of interest. Of 31 cases of the latter type, 16 were males and 15 were females; 19 were under 10 years, the remainder between 10 and 16 years of age. Nine of the patients fell from windows, one to six stories from the ground; ten fell from fire escapes, down flights of stairs and the like; four were thrown from carriages or run over. In the remaining cases the history is indefinite. It may be noted that a large proportion of the patients have been treated within a year. This is explained in part by the more accurate diagnosis. Formerly, cases of this type were usually classed as epiphyseal coxa vara, and fracture, if present, was thought to be a consequence of preceding weakness and deformity. It is now evident that the fracture is the primary, and not the secondary, cause of the disability. So also, it may be assumed that unilateral coxa vara of the ordinary type in which the deformity involves the entire neck, in non rhachitic subjects, is usually

induced by injury. Coxa vara, as thus restricted, will lose in great degree its exceptional character and will correspond more closely to the similar distortions of bones of the lower extremity, which, induced by rhachitis or other weakness in early life, develop under favoring conditions to greater deformity during growth, particularly in adolescence.

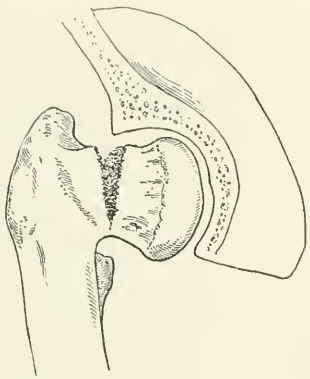

FIG. 7.—Fracture of the neck of the femur, illustrating as contrasted with epiphyseal fracture the integrity of the joint, the effect of deformity in limiting the range of abduction and the necessity for restoring the normal angle if function is to be regained.

The operative treatment has already been described. Its details vary slightly in different cases. An incision about five inches in length is made downward from just outside the anterior superior spine in the line between the tensor vaginæ femoris and the gluteus medius muscles. When these are separated the anterior surface of the joint is exposed and is opened by a straight incision in the line of the neck. The extremity of the neck is at once brought into view, but the head is almost completely concealed, lying below and behind it. Thus the removal of a thin section of bone is often necessary to permit the insertion of a chisel with which the fragments must be pried apart to permit replacement by abduction and inward rotation of the shaft. In most instances they are adherent, as if the fracture were incomplete, or as if there were partial repair. The periosteum on the posterior surface appears to be uninjured, and when the parts are brought into normal relation with one another, the tension is sufficient to hold them firmly, the head following the movements of the neck in a normal manner. The wound is closed in layers, and drainage is not essential. A plaster spica bandage is applied to hold the limb in moderate abduction and in the attitude that most perfectly apposes the fragments, usually extension and inward rotation. The patient often begins to walk about at the end of two or three weeks. The plaster support is usually retained for about two months. Crutches are used for several weeks longer, but as the structure and angle of the neck are normal, weight may be supported much earlier than if the small part of the neck were weakened. Massage of the atrophied muscles, active and passive movements, are valuable aids in restoring function.

Forcible manipulation under anesthesia may in some instances be required if the range of motion is limited by adhesions, within or without the capsule. If, however, the operative adjustment of the fractured surfaces has been perfect, eventful restoration of function may be anticipated even if the after treatment is far from satisfactory.

In order to complete the presentation of fracture of the neck of the femur in early life, and lest it may appear that foregoing cases represent the subject, several other cases will be selected from a large number in which the injury was outside the epiphyseal cartilage.

CASE XII. A boy eight years of age was brought to the Polyclinic by his physician on October 30, 1901. Three weeks before he had fallen from a fire escape, a distance of about fifteen feet, injuring the left hip. After a short period of disability he began to walk about, but as the limp and discomfort persisted, further treatment was sought. On examination, a half inch of shortening of the limb could be demonstrated, explained by a prominent and elevated trochanter. All movements were restrained by muscular spasm, but the range of abduction was completely lost. Under anesthesia, the restriction due to muscular spasm disappeared, leaving only the limitation of abduction, caused evidently by the contact of the depressed femoral neck with the rim of the acetabulum. This resistance was gently and slowly overcome by forcible abduction under traction, and when the normal limit was reached a plaster spica was applied. The child, who was treated as an out-patient, soon began to walk about. The support was removed two months later and a perfect functional cure resulted. This case is introduced because it was the first in which the opportunity was offered for testing the method of correcting the deformity of incomplete fracture of the neck of the femur, which I had suggested in 1897 (*Annals of Surgery*, June, 1897).

CASE XIII. A slender, well-formed boy 17 years of age, an amateur acrobat, was admitted to the Hospital for Ruptured and Crippled in March, 1908. In the previous October he had fallen from a tight wire a distance of about thirty feet, injuring the right hip. He was taken immediately to a hospital and after an interval of ten days a plaster spica was applied. Three weeks later this was removed, and the patient was discharged with a diagnosis of impacted fracture of the neck of the femur. He was soon able to limp about without support, but as there had been no increase of strength, further advice was sought. The patient presented the shortening and peculiar helplessness, combined with free mobility, characteristic of ununited fracture. On opening the joint it was apparent that, as in similar cases in older subjects, the neck had in great part been absorbed. The fragments were freshened and were fixed in apposition by a drill passed through the trochanter. A plaster spica was applied which was removed eight weeks later. On June 20th the patient was discharged on crutches. At the present time, union is firm. The patient bears weight upon the limb without discomfort, there is no deformity and a fair range of motion. It is proposed shortly to remove the drill and at the same time the restriction to movement will be overcome by forcible manipulation. This case is of interest from several points of view. It illustrates the logical result of ineffective treatment. Non union and absorption of tissue so often observed in older subjects and explained by a deficiency in circulation, are, in all probability, accounted for by separation of the fragments and by friction upon the exposed neck which has been softened in the futile effort at repair.

CASE XIV. A boy, 15 years of age, came to the Hospital for Ruptured and Crippled on July 24, 1908. In January he had jumped from a roof, a distance of fifteen or twenty feet, injuring the right

hip. He was taken immediately to a hospital where a diagnosis of fracture of the neck of the femur was made. A plaster spica was applied with the limb in the line of the body, supplemented by traction. Treatment was continued for eight weeks, and in June he was discharged from the hospital. On examination it was evident that the fracture had not united, there were two inches of shortening. Operative treatment was refused. This case is of interest in connection with the preceding, as demonstrating the fact that at the hip joint, as elsewhere, apposition of the fractured surfaces is the first essential for repair. The treatment that should have been followed, in my opinion, may be outlined again as follows. The patient should have been anesthetized and placed upon the support used for the application of a plaster bandage. The limb should then have been flexed and rotated inward in order to disengage the possible interposition of the anterior wall of the capsule and psoas muscle. Then by direct traction on the limb and pressure on the trochanter, the shortening, as demonstrated by actual measurement, should have been overcome. The limb should then have been abducted to the full limit, and while traction was exerted, upward pressure on the thigh should have been made to align the fragments against the resistant anterior border of the capsule made tense by the abduction and traction. In this attitude a firm, well-fitting plaster spica, accurately moulded about the pelvis and trochanter and supported beneath by a bar of steel, applied after the manner of a Thomas hip splint, should have been applied. The same treatment should have been employed in Case XII, even if the fracture were thought to be impacted; for shortening always implies a lessened angle of the neck, which is, in itself, the cause of subsequent disability. Furthermore, this method should be employed in adult cases if it is not contraindicated by the age or other disabilities of the individual. (MEDICAL RECORD, March 19, 1904.)

CASE XV. A well-formed, healthy boy, 12 years of age, without a trace of rhachitis, entered the hospital on August 12, 1908. About two years before he had fallen from a wagon, injuring the left hip. He says that he suffered some discomfort, but did not inform his mother for two months, because a brother was under treatment for hip disease. He was then taken to a hospital where, after a long interval, a hip brace was applied. This brace was removed at another institution after it had been worn for several months. At the present time there is only occasional pain and a slight limp. The examination showed an elevated and prominent trochanter with three-quarters of an inch of shortening. Motion was free and painless, except in abduction, which was almost completely restricted. This case was evidently one of simple depression of the neck of the femur, which might be classed as coxa vara but for the fact that the deformity was unilateral in a healthy subject following immediately on a fall and persisting since that time. The case is one of the type to which I have called attention, in which incomplete fracture in a child, like a green stick fracture elsewhere, does not cause immediate or complete disability. An *x*-ray picture was taken, showing right angular depression. A reproduction was made in stiff paper, and a cuneiform section was cut, the apex at the trochanter minor, of the exact size necessary to restore the normal angle, in this, as in most cases the base being about three-quarters of an inch. On August 18, the wedge of corresponding size having been removed, the limb was gently abducted. When the trochanter came into contact with the rim of the acetabulum further abduction of the shaft closed the opening and restored the normal contour of the bone and the range of abduction. The wound was sutured and a plaster spica was applied. This operation assures the anatomical contour and thus permanently restores function, as has been proven in many instances since it was first devised.

It may be noted that in cases of fracture of the neck, outside the epiphyseal junction, the joint has not been opened except for non union. The reason is, that in cases of this type the head of the femur being intact, the joint surfaces are not directly involved. It is possible, therefore, in recent cases, to overcome the deformity by manipulation or by the operation on the shaft, if consolidation has already taken place. In epiphyseal fracture, on the other hand, the joint is so disorganized by the fracture that function must be much impaired or lost unless the proper relation is restored.

It has been stated that in the cases of epiphyseal fracture treated by open operation, it was impossible even with the advantage of direct inspection to disengage the adherent fragments. It does not follow, however, that flexion, abduction and inward rotation of the limb under anesthesia, in the manner described, might not be fairly effective soon after the injury, as in the one case reported. This is a consideration of importance since the open operation is not likely to be undertaken by those who may have the opportunity for immediate treatment of these cases. Nor should it be resorted to until it is apparent that this treatment is ineffective. It has been demonstrated, however, that manipulative reduction requires early diagnosis. In not one of the cases of epiphyseal fracture had a diagnosis been made before the patients came under observation and, with a few exceptions, the statement is true of the much larger number of cases of the other type. This primary diagnosis will be more generally made when it is officially recognized that the neck of the femur is a weak point in the skeleton, and that it may be broken by slight force advantageously applied, in early and middle life, as well as in old age. Furthermore, that a fracture of the neck of the femur by no means implies immediate or complete disability, and that persistent limp and discomfort following an injury to the joint are more readily explained by fracture, than by contusion or disease.

The cases outlined in this paper have been selected to illustrate four types of fracture of the neck of the femur in early life as they are likely to be presented for treatment.

1. The unusual cases, in which a correct diagnosis permits immediate correction of deformity by manipulation.

2. Cases in which the fracture has consolidated, the deformity being of the coxa vara type which may be corrected by cuneiform osteotomy of the shaft without disturbing the joint.

3. Ununited fractures which require direct operation for the purpose of fixing the fragments.

4. Epiphyseal fractures, in which as a rule the capsule must be opened.

The aim in the treatment of all the cases has been functional cure, to which the removal of deformity, by means adapted to its character and duration, must be the essential preliminary.

The results attained, as contrasted with disability, distortion and non union even, in cases of the same

favored class, in which the treatment or non treatment had followed accepted methods, encourages the belief that the application of the same principles to all cases in which the condition of the patient permits local treatment, would lead to a corresponding improvement in the final results.

283 Lexington Avenue.

TWO IMPORTANT ANGIONEUROSES.*

By ARTHUR J. WHITING, M.D. (Edin.), M.R.C.P. (Lond.).

LONDON.

PHYSICIAN TO THE PRINCE OF WALES'S GENERAL HOSPITAL, LONDON; ASSISTANT PHYSICIAN TO THE MOUNT VERNON HOSPITAL FOR CONSUMPTION AND OTHER DISEASES OF THE CHEST, LECTURER IN AND DEAN OF THE NORTH-EAST LONDON POST-GRADUATE COLLEGE.

THE two angioneuroses which I wish to discuss are acroparesthesia and angioneurotic edema.

The former is, I suggest, important because it is frequent and incapacitating, the latter because it may be the cause of sudden death, and that possibly it may be transmitted to the children's children.

In this group of diseases, using the term disease for the present as synonymous with symptom-complex, we assume on account of the obvious disturbance of the motility of the blood-vessels that the vasomotor or sympathetic nervous system is primarily implicated, and because no anatomical substratum of this disordered activity has hitherto been recognized we have been accustomed to consider them as neuroses of the vessels. It may safely be said that such an anatomical basis will probably ere long be demonstrated, but it may also be safely said that at the present day disorders of the sympathetic and trophic system are a vast and almost unexplored sea.

It may be well at the outset to attempt to classify the angioneuroses. On one basis they may be divided into the objective and subjective, the objective on the one hand including such types as the well-known condition "dead fingers," the red and painful swelling of the feet known as erythromelalgia or paralytic vasomotor neurosis of the extremities, the even better-known Raynaud's disease with its local syncope and local asphyxia, otherwise called symmetrical gangrene and angioneurotic edema with its circumscribed edematous swellings of the skin and mucous membranes; and the subjective on the other hand represented by the type acroparesthesia, sometimes called spastic vasomotor neurosis of the extremities with its pain and uncomfortable sensations referred to the hands.

It will be clear even from this classification that the defect of vasomotor nerve influence may be manifested either by contraction or dilatation of the vessels, angiospasm or angioparesis, and on this basis too a classification of a sort may be built up. Thus among the angiospasms we must rank "dead fingers," the early stage of Raynaud's disease, and probably acroparesthesia; and among the angioparesis, erythromelalgia, late Raynaud's disease, and angioneurotic edema.

Acroparesthesia.—The name acroparesthesia was given to the symptom-complex we are now considering less than twenty years ago by Schultze and it describes the conditions fairly well except that the sensations referred to the extremities, the hand particularly, are less frequently or at any rate less insistently paresthesiæ of tingling, creepin, burning or distention than actual pain, and according to my own experience, at any rate, the abnormal sensation of subjective numbness is more frequent than the other sensations more properly described as paresthesiæ.

I do not intend to offer many details of individual cases, but will give the notes of one (there is a remarkable family likeness in the cases) and give merely the salient points of the cases of other patients.

Mrs. P., aged 31, the wife of a laborer, came to hospital at the beginning of one April complaining of numbness and pain in the hands, which came on at night after getting warm in bed, especially after having done washing during the previous day. She had suffered in some degree from such sensations for four years, but they had latterly become more distressing. There was also, she said, some swelling of the hands at the time. She had to work hard, and was much hampered in her work because she was unable to grip anything till midday. Her sleep was much disturbed. She improved under treatment and less work, and particularly when she gave up doing washing for other people. She discontinued attending hospital about the end of June.

On November 22 she returned with the story that during the cold and wet weather of the few days previous she had had tingling and "numby" sensations of the hands, but they "did not swell yet."

On February 7 (next) she reported that her hands had been worse during the frosty weather. The pains now went up to the shoulders, and in the morning she often failed to hold things in her hands, although she could feel them. She was frequently breaking crockery and had more than once cut herself with the fragments. She had not been doing more washing than usual. Sensations of numbness and gnawing in the hands began directly she got into bed, so that during the night after her weekly washing day she could hardly sleep at all, and the sensations remained insistent for two or three days after. The hands swelled and went a little shiny at the same time. She was unable to finish dressing in the early morning and had to come downstairs, have breakfast, and then return to the room to complete her toilet. Hearing in the out-patient room the complaints of another patient, she said when her turn came "that lady must be like I am."

Another patient, a woman of 45, said that during the night after having done her own washing she got no sleep at all. She got some relief by letting her hand (one was especially affected) hang down out of bed. When the pain was bad she was unable to pick up anything or even carry anything with it. During a month of very cold weather the sensations affected her feet, and for nearly a week she had hardly any undisturbed sleep. The pain in one hand particularly would wake her up a dozen times in the night. During the whole of this month her fingers felt numb and she could not use them properly for anything.

Another, a woman of 38, said that after a day's washing she would get hardly any sleep the whole night, she could cry with pain in the hands and would not know where to put them. She also complained of a "dead" and a burning feeling. The sensation went up to the elbow on one side, but not beyond the wrist on the other.

Another patient, a woman of 32, began to suffer in the same way two or three months after having undergone hysterectomy at the hands of my colleague, Dr. Arthur Giles. She complained of pins

*A lecture delivered at the Medical Graduates' College and Polyclinic, London, October 28, 1908.

and needles and numbness in the hands, also of a hot bursting feeling, but especially of pain coming on in the middle of the night. She often had to get up for two or three hours at a time, when she obtained a little peace and was able to sleep again for an hour or two. She was able to dress herself in the morning, but would often drop things. The sensations usually disappeared about fifteen minutes after getting up, but might return during the day, though never so severely.

The patients so far have all been middle-aged women, and the rule is for women to be affected about ten times more frequently than men. Of 162 cases collected by Cassirer only twelve were in men, and of 184 cases 150 were between 30 and 60, but one was a child of 7 and another a woman of over 70.

I have recently met with the condition in a hewer of marble which seemed to depend on the handling of the cold stone, and in a busy medical practitioner after motoring, occurring in his left hand, used in holding the wheel. The pain and sensation of pins and needles would wake him up in the night and were not due to his lying on his arm, because they would occur if he rested his arm on a pillow.

About three-quarters of the total number of cases have occurred in washerwomen or charwomen, or other middle-aged women engaged in arduous work with their hands and exposed to the varying temperature of hot and cold water, or it may be of cold air, as in the case of seamstresses. Indeed, of 43 cases collected by Collins, several could bring the sensations on by placing their hands in cold water. Other apparent etiological factors have been anemia, alcoholism, influenza, and disorders connected with the sexual life—the climacteric, parturition, and pregnancy. An illustration of the latter group I have just given you, and Cassirer has met with five that followed panhysterectomy among say 200 cases.

The attacks usually occur in the early morning, between 4 and 6, but the sensations may persist throughout the day, or sometimes they commence after the patient has awakened from an afternoon siesta. The rule is for them to be much worse during cold weather and to disappear in hot weather.

They may be referred to the tip of the tongue and the lips, but the characteristic distribution is in the fingers, more rarely the feet, usually in one hand more than the other and occasionally spreading to the elbow or even the shoulder.

It is, as I have said, a subjective malady with creeping, tingling, burning, itching sensations, or a feeling as if the extremity were swollen and would burst with generally, at any rate in patients that come to hospital, more or less severe pain. In some cases, however, there may be such objective signs as anesthesia or blunting of sensibility (hyperesthesia) and signs of vasomotor disturbance as whiteness and coldness of the fingers. The cases may then be grouped into paresthesia cases proper, pain cases, hyperesthesia cases, and vasomotor cases.

There is nothing definitely hereditary in this symptom-complex, there is no morbid anatomy, and no quite definite pathology. The condition seems to me to be comparable with occupation neuroses, the stress falling on the vasomotor system in people who use their hands in media of greatly varying temperature. There seems to be usually a vasomotor spasm and a coincident or consecutive stimulation of sensory nerve endings as the schoolboy's hand tingles after snowballing. There is evidence too of a toxemic predisposing factor as in urticaria. The toxic factor, the temperature factor, and the fine movement factor seem to be the chief.

There is really very little difficulty in the diagnosis—a peripheral neuritis is, I suppose, most often suspected, but the coming and going of the symptoms and the absence of all muscular atrophy are alone sufficient to differentiate the two. The great difficulty in classifying the cases is probably occupation neuroses, as in our marble worker, but, as I have said, the two really seem to run into each other.

Improvement under suitable treatment is the rule, but the cases may last for many years though they rarely progress.

That suitable treatment is really to change the mode of life; let the patient reduce or discontinue her washing occupation, as a clerk with writers' cramp might be advised to use a typewriter, or a house painter with lead palsy to take to clerking. It has seemed beneficial to remedy dyspeptic difficulties and counteract as far as possible intestinal autointoxication. General tonics and perhaps bromide for the nervous instability; general exercises, friction with liniments, electricity, the interrupted or constant current or static, even warm hand baths, may all be tried, but they are measures of secondary importance. So much for this important because disabling angioneurosis.

Angioneurotic Edema.—Now let us consider the second, angioneurotic edema—important because in many instances it has ended life in a fashion nothing short of tragic, and also because it may be directly transmitted from one generation to another, with fatal cases even in the fourth and fifth and more.

It is one of the objective angioneuroses inasmuch as it is characterized by the occurrence of localized edematous swellings.

Case I.—A girl, aged 19, a domestic servant, was admitted into hospital on account of recurring swellings of the face and limbs. Seven years before her right arm had swelled so rapidly that it was necessary to slit up the sleeve at once. On the next morning her left eye was swollen. From that date she had been subject to similar attacks every third or fourth week, affecting the limbs, including the hands and feet, the lips (as shown in the photograph I send round), the ears, nose, eyelids, vulva, throat, or the tongue. The swellings were on an average about 1 inch across but varied considerably in size, and they did not pit on pressure but were somewhat painful and tender. She was sometimes warned of their coming by a burning and tingling sensation in the part to be affected. Sometimes she suffered from colic but never from nausea or vomiting. There was no history obtainable of anything of the kind in her family. There were slight enlargement of the spleen, slight leucocytosis and marked dermatographia, but nothing else abnormal. During her stay in hospital she had an attack of edema nearly every day, affecting the parts named. She was treated with calcium chloride in 10-grain doses, three times a day, but without any evident improvement.

This is a fairly representative case. The pain and tenderness are unusual, and the perspiration of the swollen hand which was observed is unusual though not unique, and I may say that corresponding secretory changes affecting the salivary glands have been noticed in some cases in which the mouth has been affected.

Case II.—Another case I will merely refer to was that of a man who suffered every few weeks in the early mornings, about 4 A.M., with a hard swelling in the side of the tip of the tongue, spreading in a few hours to the whole of that half of the tongue, and, after the sudden death of his daughter by lightning, more frequently (every few days) and more widely involving the lip and cheek. He, too, had an aura two or three hours before an attack, taking the form of dryness of that side of the mouth and a metallic taste as far as I know a unique occurrence. There was no family history of such attacks. He greatly improved under thyroid extract and when I last heard from him he had not had even a slight attack for over two months.

Case III.—On September 23 last I was asked by Dr. Bazett of Hendon to witness the necropsy of a man who had died suddenly early that morning from sudden obstruction to the air-way in the throat. He had been called up to see the man who was said to be choking. When he arrived (as recorded in a clinical note in the *Lancet* of October 12, 1907) he found the man dead, to all appearances, from suffocation. With his finger Dr. Bazett felt that the parts around the glottis were much swollen and when he attempted artificial respiration the resistance was so great that it gave him the impression as if a wind-bag to which there was no outlet was being pressed. The eyelids were much swollen, as also were the cheeks and lips, especially the lower, and the neck appeared to be twice its natural size. There was no swelling of the rest of the body, the urine was free from albumin. The man, who was 33 and a gardener by occupation, had been liable to sudden swellings in various parts of the body since he was a boy of six, following on an attack of scarlet fever. Also since then (I quote the account given by the relatives and printed in the *Lancet*) he had been subject to regularly recurring fortnightly attacks of most violent abdominal colic. The widow described his appearance in these attacks as "like a woman in labor." They did not last over 24 hours. Never, apparently, accompanying them, but often preceding them by one or two days, and sometimes unassociated with them, occurred sudden swellings of various parts of the body, subsiding in the 24 hours, usually in the hands, or the thighs, or the scrotum. The thighs would then meet in the middle line. These swellings were apparently induced by any slight injury or by chill. They were so tense that they "felt as if the skin must burst." In childhood they had sometimes attacked the face and throat, but never since. . . . On the evening of September 21 a bicuspid tooth which had been aching was extracted by a skilful local practitioner, leaving a healthy looking gum. On the morning of the 22d the mouth naturally felt sore and there was a little external swelling on the cheek of that side, but the patient felt quite well and took a long cycle ride. Later in the day the swelling had extended over that side of the face, including the eyelid of that side. Toward night the neck began to swell and then the throat. The patient was not alarmed as he said "it would go down as it had before." He went to bed and fell asleep, but breathed heavily. About 2 A.M. on the 23d he suddenly woke choking, sprang out of bed, and called excitedly to his wife to put a spoon, her finger, or something down his throat, then tried to put his own finger down, then lay on the bed, and while she rushed for help passed away. There was no family history obtainable pointing to any hereditary influences. At the necropsy, made 42 hours after death, the swelling of the external parts had largely subsided, but it was still marked in the lower lip. There was great swelling of the epiglottis and arytenoepiglottidean folds; the appearance was that of two elongated and one rounded bladder filled with a yellowish fluid and closely pressed together. All the body organs were healthy; the appearances were those of a normal subject who had died from suffocation. The specimen of the fauces and larynx is now in the museum of St. Mary's Hospital, but the appearances are much changed owing to shrinkage.

These, then, are fairly illustrative cases of the condition first described probably by Graves of Dublin in 1848, but first thoroughly studied by Quincke, who published his results in 1882, under the name of acute circumscribed edema, which since has been known on the Continent as "Quincke's edema."

I need not, I think, further elaborate the clinical picture. The attacks show a certain periodicity, the average interval among a large number of cases being about three weeks. Males are rather less frequently attacked than females in America, but in the old country and on the Continent the reverse obtains. The age is usually early adult life. The attacks most often begin between 3 and 4 A.M. The recognized exciting causes include heat and cold and slight injuries, hence the seat of election is generally on exposed surfaces. Periodical attacks of severe colic are a frequent concomitant or antecedent, as in the case I have quoted, and under the latter condition they may seem very mysterious. Lavage has been practised to relieve the abdominal pain, and in one case recorded by Morris (*American Journal of the Medical Sciences*, 1908, Vol. 130, p. 382) a highly edematous portion of gastric mucous membrane was accidentally removed by the stomach tube. In another typical case with gastrointestinal involvement recorded by Harrington (*Boston Medical and Surgical Journal*, 1905, Vol. 152, p. 363) the abdomen was opened during a crisis on account of the possibility of disease of the gall-bladder when a thickening of the whole circumference of the lower wall for 2½ inches was found in the ileum increasing its diameter twofold.

Some of the cases of the disease as those I have quoted are solitary but probably more than half occur in families. Professor Osler records 22 cases occurring in five generations of one family including only 36 members, and Dr. Ensor 33 among 80 members of the five generations of another family.

Sudden death in certain solitary cases of angioneurotic edema is a not very rare termination, as in Case III, but it is even less unlikely in the family cases. Of 110 family cases collected by Dr. McDowell of Auckland, New Zealand, for the purpose of a graduation thesis and while a member of the North-East London Post-Graduate College, to whom I am indebted for many of the historical facts in this lecture, no less than 30 died from suffocation following sudden edema of the larynx.

It would be possible to give you a harrowing account of these cases, but I will mention only one or two, and merely say, to give you an idea of frequency, that among the 33 cases collected by Ensor there were 12 suddenly fatal.

Of a family of 12 members spread over four generations recorded by Mendel (*Berliner klinische Wochenschrift*, No. 48, p. 1126) nine persons were affected, and six of these died from edema of the glottis, the patient's great grandfather, his son and

daughter (the patient's grandmother), her son and daughter (the patient's father and aunt), and a son of his grandmother's brother. The brother of the grandmother died when 40, after the extraction of a tooth (as in Case III). Of his four children one son died at 22 from edema of the glottis, while two other sons, aged 51 and 48, were then alive but suffering from attacks nearly every week and in dread of death in the family manner whenever the edema was in the neighborhood of the throat or face. The other group is a father and his only child, a daughter, who, as recorded by Griffith (*British Medical Journal*, p. 1470), both died from edema of the glottic region. In the case of the daughter a laryngoscopic examination was made during an attack in which the epiglottis and aryepiglottidean folds were so much swollen as to obscure the vocal cords. This was in 1886. Other attacks occurred in 1890 and in 1891, when all that could be seen on laryngoscopic examination were three rounded lumps, pale, tense, and jelly like (as in Case III); on the next day the swelling of the face was subsiding and on the following day the larynx was of normal appearance. On February 20, 1902, at 10:30 A.M., she complained of slight swelling of the throat; at noon her husband found her sitting on the floor preparing to spin a top for her child and breathing easily; suddenly she dropped the top, tried to speak, but was unable to do so, clutched her husband's throat as if to show the seat of her own distress, became blue in the face, and died almost at once. Her mother who came into the room just as she was expiring said that it was just in the way that her father had died. The necropsy showed great edema of the whole larynx, its sides being in contact, and the submucous layers and muscles were markedly affected as well as the mucous membrane.

In regard to the pathology of the condition but little can be said, and I must be content with saying even less. A pure vasomotor instability seems certain though neither pallor nor redness are conspicuous; an interference (call it trophic if you like) with the lining of the vessels accounting for the edema seems also probable; a toxic factor as Quincke has always strongly maintained seems also clear, especially so in some cases, and there seem to be affinities with asthma and even the acute suffocative catarrh of Laennec, for in some cases there has been implication of the bronchial mucous membrane.

As to diagnosis in well-defined cases no difficulty could well arise. Some of the slight cases might be confused with severe cases of urticaria, but the clinical phenomena of the two are really quite different but must not further detain us.

As to prognosis it is good as regards life if the skin only is affected; it is unfavorable if the respiratory mucous membrane be implicated, and distinctly more so in the family cases.

But little must be expected at the present time from treatment. Much the same general treatment as that suggested for acroparesthesia should be tried. On a theory of excessive venous permeability I have tried calcium chloride but without definite result. Mendel especially recommends aspirin to counteract autointoxication from intestinal putrefaction; Cassirer menthol and camphor. Ichthyol in pill has been recommended as in urticaria, and arsenic has apparently done good. Thyroid extract, as I have said, seemed of service in one of my cases. Various local measures in the way of gargles and lubricants have been advised for the throat attacks, but the main precautionary measure would be the wearing of a tracheotomy tube permanently, which is a serious matter to undertake in emergency; failing intubation apparatus, a tracheotomy, however extemporized, followed by artificial respiration, are clearly indicated.

142 Harley Street.

HEADACHES OF OCULAR AND NASAL ORIGIN.*

By CHARLES GRAEF, M.D.,

NEW YORK,

PROFESSOR OF OPHTHALMOLOGY, FORDHAM MEDICAL COLLEGE; OCULIST AND AURIST TO FORDHAM HOSPITAL AND TO LINCOLN HOSPITAL.

In any consideration of headaches a combination of those of ocular and nasal origin is, to my mind, peculiarly appropriate, because it is a fact, only lately beginning to receive proper recognition, that these organs have frequently a marked association in the production of such symptoms. It is safe to say that of headaches of all kinds, much the largest percentage have their origin in the eyes, or nose, or both.

So much has been written and said on the subject that the lay as well as the medical mind is now fairly keenly alive to the importance of a thorough examination of the eyes in cases of troublesome headaches, but it is not at all generally recognized that in many cases the nose plays an important part in causing these reflex pains. The point is well worthy of emphasis. The close anatomical relations readily explain why pain due to nasal disease may be attributed to the eyes. The orbits are largely formed by the nasal walls and are closely surrounded therefore by the accessory sinuses, while both the blood and nerve supplies of these organs are largely derived from common sources.

As with headaches of purely ocular origin, the practitioner now recognizes that the patient need not necessarily have had his attention drawn to the eyes by abnormalities of vision, so in nasal cases, the absence of symptoms obviously due to the nose must not be held to exclude this as an etiological factor.

In the eye the chief causes of headaches are congenital in origin, yet the patient may not suffer from this reflex until maturity is reached, or even until later in life, perhaps after an attack of general illness. Anything which lessens vitality is likely to betray the existence of previously hidden faults in these organs. A young mother, for instance, who has heretofore been able to overcome, by sheer effort of her ciliary muscle, a hyperopia of several degrees, finds to her alarm that her new duties have made demands on her strength which lessen this power to the point where she can no longer focus light on the retina, and she is frightened to observe that her sight is apparently failing. A similar experience often occurs in the case of a child who suffers paresis of these, with other muscles perhaps, from the toxins of diphtheria.

I do not wish to take up time with any prolix attempt to explain how headaches are caused by ocular faults, but it is necessary to recall to your minds the fact that nature has given man a special ability to see clearly with two eyes at once—binocular single vision. No other animal possesses this ability to like extent, and comparatively few types begin to approach it. It is interesting to note that

*Read at a meeting of the Bronx Medical Association.

among the vertebrates, the higher the order, the more closely the plan of semidecussation of the optic nerve fibers resembles that found in man, and it is on this arrangement that binocular single vision depends. To obtain this visual ability by having the two eyes acting comfortably in concert certain conditions are absolutely essential: the two eyes should have similar focal power for light, for instance; this requires that they be of like form, and evenly matched as regards clearness of media, curvature of cornea, lens, etc., of equal visual acuity from a retinal and optic nerve standpoint, and that their movements be closely coordinated in direction and extent.

The power of focusing images seen by two normal eyes into a composite whole, is analogous with the clear view one gets when looking through the prisms of a stereoscope at two similar pictures mounted on a suitable card. It makes the view clearer and sharper by adding a third dimension and giving us depth instead of a flat picture. Nature, by giving us the equipment which makes possible such vision, implants in us the wish to secure it. We are not born with it. The eyes of babies for some time after birth are inclined to wander vaguely about without coordination of movement, but later on when, in the language of the nurse, the child "begins to take notice," this fusion power is being acquired. Some children, indeed, never acquire it, and this is one of the causes of cross-eyes; others again, because of faults in one or both eyes (and I have suggested some of the numerous points where such faults may lie), either acquire little of this power of fusion, or because of difficulty in maintaining clear binocular vision, soon lose it and consequently develop crossed-eyes or other symptoms. You will appreciate then that any deviation from the normal in the eyes interferes seriously with a power which is so much a part of our well-being, that we, for the most part unconsciously, make strenuous efforts to overcome such interference. In a word, if the fault in the ocular apparatus is so marked in kind or degree that the patient cannot overcome it, he yields to necessity and gives up the effort, suffering then, as a rule, only a corresponding loss of vision. If, on the other hand, he is able by muscular and nervous effort to secure better sight, he is likely to keep up that effort, and realizing that this exhausting task is being carried on through every waking minute, we can understand that such an individual is almost certain to suffer from reflex symptoms, of which headache is one of the commonest.

With these facts before us we can give due weight to the influence of heredity in these sufferers. There is no other part of the body in which peculiarities of form are so constantly transmitted from parent to offspring as in the head. Abnormalities in the orbit and its contents, incorrect attachment of muscles to the eyeball, one eye on a slightly higher plane than its fellow, etc., are correspondingly likely to be handed down.

In analyzing cases of "asthenopia" it will be noted that there is no constant relation between eyestrain and the degree of fault discovered. The symptoms complained of vary in nature and severity with the individual, depending somewhat on his occupation, his surroundings, the amount of use and abuse he gives his eyes, and very often largely on the personal equation to be reckoned with in every patient. The phlegmatic individual will get on comfortably with ocular faults of a degree which drive his more sensitive and nervous neighbor wild with pain. Often enough, a patient who suffers only from mildly inflamed eyes, lowered vision, and some blurring of print when reading, will prove to have faults of refraction requiring practically the same glasses as are needed by another whose eyestrain has caused him the profoundest misery through frequent attacks of frontal or occipital pain, or in other cases the severer forms of so-called sick or nervous headache.

Even in patients of similar temperament these striking differences are noticeable, and study of the cases will often reveal some such added force as a uric acid diathesis. Many of our patients in city life trace the immediate cause of their symptoms to overuse of the eyes in poor light or under the trying glare of excessive illumination by electricity.

Again, the nervous patient who has to contend with an ocular fault will have his sufferings much increased, if to the ocular reflexes are added the distressing effects of imperfect nasal conditions. In some of these the general health becomes greatly impaired and it is quite common for such individuals to confuse cause and effect. They believe such eye symptoms and nasal defects as they have noticed are the result of their bad head or general ill-health, instead of the reverse.

In considering the likelihood of any given case of headache being due to ocular or nasal faults, the nature and location of the pain are of comparatively little help. Simple eyestrain from errors of refraction commonly causes aching over the brows, but pain in the occiput, in one or both temples, deep in the head at the back of the eyes, or a general sick headache, may arise from the same source. Pains in the vertex are commonly attributed to the pelvic organs, but study of the sphenoid sinus goes to prove that in a number of these cases this is the real source of difficulty.

Other patients in considerable numbers suffer from headaches where no ordinary cause of eyestrain can be made out, and in them pathological conditions of the deeper parts of the eye are often found. Among these is disease of the macula or other parts of the retina, accompanied at times by hemorrhages or signs of optic neuritis. Of very great interest and value in this field are the studies of the ocular signs in cases of headache due to general arteriosclerosis. Persistent high arterial tension in these cases is very likely to cause changes of a characteristic type in the ocular fundus. So well marked are these in many cases that they prove of much diagnostic help.

De Schweinitz divides these appearances into: (a) suggestive signs; (b) pathognomonic signs.

In the first class are the cases showing uneven caliber and undue tortuosity of the retinal arteries, increased distinctness of the breadth of the artery, an unusual light color of the breadth of the artery, and alterations in the course and caliber of the veins.

Pathognomonic signs are: Changes in the size and breadth of the retinal arteries, giving them a beaded appearance; distinct loss of translucency; decided lesions in the arterial walls, consisting of white stripes in the form of perivasculitis; alternate contraction and dilatation of the veins and especially indentation of the veins by the stiffened arteries, just as a rubber tube would be indented by a solid rod laid across it. Sometimes the vein is flattened at the point of crossing, or merely pushed aside, or its caliber is contracted so that there is an am-

pulliform dilatation beyond the point of crossing. The veins, too, may show borders of white stripes and be exceedingly tortuous. Edema of the retina in the form of gray opacity about the disc, and hemorrhages following the course of the vessels are seen in extreme cases.

Probably in no class of patients can the ophthalmologist be of more help to the practitioner than in this. If to the clinician's study of the pulse, the character of the first sound at the apex and the second sound at the aortic area, and perhaps sphygmographic tracings and instrumental measurements of the arterial tension, can be added the sure evidences seen by the ophthalmoscope, an early diagnosis of these important conditions is made certain. Although disease in the retinal vessels cannot in every case be held to prove a similar state in the cerebral or other vessels, its existence is very suggestive. In at least one of the cases in which I have personally ventured to make such a diagnosis from the ocular findings, a cerebral hemorrhage about a year later made a striking verification of the value of these signs.

With the nose and its accessory sinuses as factors in causing headaches time does not permit me to deal at any length here, but these few points I will venture to add:

Irregularities of the nasal septum and turbinals, resulting in points of pressure between the middle and lateral walls of the nose, were long since recognized as causes of reflex pains, but the accessory sinuses are now admittedly even more often responsible for such symptoms. These cavities are lined with a delicate mucosa, a modified form of that seen in the nasal chambers. Irritation of these membranes causes swelling and exudation very like that present in acute conjunctivitis, and the cavities are poorly equipped with natural drainage; indeed, the small openings by which they communicate with the nose are probably no more intended for drainage purposes than is the Eustachian tube meant to drain the middle ear. Their real purpose is to permit interchange of air between nose and sinus.

With the aid of cocaine and adrenalin we are now able to probe these various sinuses and determine with fair accuracy what conditions are present. Again, we should bear in mind the close vascular connection between the upper nasal passages and the meninges. Congestion of the upper part of the nose not only blocks the air passages and so produces points of painful pressure, but it interferes with the circulatory flow from the meninges. All of us have felt the effects of such engorgement in attacks of coryza. The venous distention is sometimes quite marked in these cases, and in many of them the congested vessels of the conjunctiva give a fair picture of what is going on deeper in the head. The passing along these channels of thrombosis and infection, with fatal result at times, especially after the use of the cautery in the nose, is also an impressive lesson as to the importance of this connection.

Disease in the ethmoid cells and sphenoid sinus is undoubtedly responsible for some cases of optic atrophy in which headache from the same cause may be the only indication of ill-health. Many of these cases are so obscure as to be termed "idiopathic."

The use of atropine in examining the eyes in some cases where catarrhal disease in the accessory sinuses is present, by drying up the secretion and thereby bringing temporary relief, is likely to give the glasses prescribed a measure of credit that is really undeserved. So marked are some of these nasal factors in many cases that the writer makes it practically a routine practice to examine both, when either of these organs is believed to be the source of headaches.

A word as to treatment. From what has been said it is very evident that little or no real benefit can be had in these cases from drug treatment. Mechanical and surgical measures judiciously selected for each case are much more to the purpose. Carefully chosen glasses, properly set in comfortable frames, are absolutely the only permanent relief from headaches due to errors of refraction, of which the commonest type is hyperopia with astigmatism. Muscular weakness, or imbalance, is also a prolific source of such symptoms and demands much care and judgment for its proper correction; not infrequently operative interference must be added to such glasses as are necessary. The physician should use his authority with his patients to break down the widespread error that sufferers, especially children, are likely to outgrow the conditions responsible for ocular and nasal reflexes. Many of the nasal cases can be cured by operation. In a still larger number, a combined study and correction of faults in both eyes and nose will be found necessary.

A TABLE OF STANDARD WEIGHTS FOR WOMEN.*

By FANEUIL S. WEISSE, A.B., M.D.,

MEDICAL STATISTICIAN, MUTUAL LIFE INSURANCE CO. OF NEW YORK.

This table is based on the study of the heights and weights of 59,525 insured women, clothed and shod ranging in height between 4 ft. 1 in. and 6 ft. 1 in., and in age between 15 and 69 years inclusive. The height and weight in every case were taken from the Medical Examiner's report. The records of 24,626 of these women were obtained from the Mutual Life Insurance Co., and the balance, 34,899, were furnished by Dr. O. H Rogers of the New York Life Insurance Co.

In the height groups those under 4 ft. 11 in. and over 5 ft. 10 in. contain so few individuals—only 578 in all—that I have eliminated them from my calculations. In the same way the last age-group or quinquennium—65 to 69—has been eliminated as it was made up of but 92 individuals. The following table shows the distribution in the various height- and age-groups of the remaining 58,855 women—the totals for all heights and for all ages being shown on the margins of the table.

The next table shows the average weight for each inch at each quinquennium, from 4 ft. 11 in. to 5 ft. 10 in. inclusive, based on Table I.—the averages for all heights and for all ages being set forth on the margin of the table.

The mean height of all the individuals was 5 ft. 4 in.—19% were of this height—while the average height was 5 ft. $4\frac{1}{4}$ in., and the average weight 133 pounds. The quinquennium 25 to 29 showed the greatest number of individuals—23%.

–10″	8	1,114	67	9,835	109	16,894	83	12,854	73	11,270
Totals for all Heights	1,690	207,461	8,913	1,129,277	13,700	1,766,855	12,448	1,650,960	9,735	1,324,828

In preparing the adjusted table, which follows, it is interesting to note that the weights of over 80% of all these women needed practically no adjustment. The age groups above 45 to 49 required adjusting practically throughout, as did the extreme height groups. The changes in the averages for combined heights and combined ages are nowhere more than one pound, except age-group 55 to 59, where there is a difference of 1.4 pounds. The average weight of all the 58,855 individuals, after all adjusting, involved a difference of less than a tenth, .056, of a pound. These various adjustments were made by close inspection and minute calculation following the course of the general curve for those heights and ages.

male tables, I took from the Report of the Special Committee of the Association in 1897 the data on insured males between 5 ft. and 5 ft. 10 in., ages 15 to 64 inclusive, put these together in a table similar to Table I., and so found that I had a group of 58,257 men with a mean height of 5 ft. 8 in., an

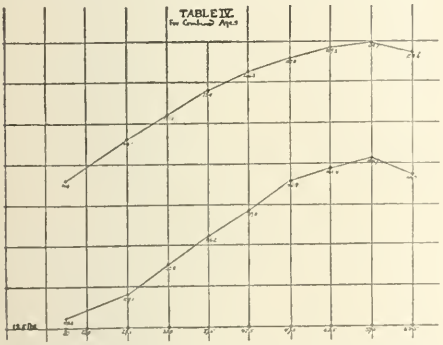

TABLE 4.—The upper line is the weight curve of 58,257 insured men, 5′-0″ to 5′-10″ high; average weight, 151.5 pounds; average height, 5′-7.3″. The lower line is the weight curve of 58,314 insured women, 5′-0″ to 5′-10″ high; average weight, 133.1 pounds; average height, 5′-43″.

average height of 5 ft. 7.3 in., and an average weight of 151½ pounds. To make the female group similar in all respects, I eliminated the first height-group, 4 ft. 11 in., and combined the age groups, 15 to 19 and 20 to 24, as in the male table. This gave me a group of 58,314 women with a mean height of 5 ft. 4 in., an average height of 5 ft. 4.3 in., and an average weight of 133.1 pounds.

It is of interest at this point to present the unadjusted weight curves of both men and women for the combined heights 5 ft. to 5 ft. 10 in.—remembering that no comparison—except one as to regularity of curve—can be made, as the average male height is 3 in. greater than the female.

The following table compares the adjusted weights of men and women of the same age and the same height—giving the number of pounds by which the women differ from the men at each age period.

You will see that as the age increases the sexes approach nearer at 5 ft., 5 ft. 1 in., and 5 ft. 2 in. At 5 ft. 3 in. and 5 ft. 4 in. they meet at age 50 to 54 and continue practically the same. At 5 ft. 5 in., and 5 ft. 6 in. they meet at 45 to 49 and continue practically the same. At 5 ft. 7 in., 8 in., 9 in., and 10 in. they do not meet, but diverge after 50 to 54, at which period they come closest together. This difference in weight in the higher inches may be explained by the fact that while these heights represent the largest classes of males they also represent the smallest classes of females. The tendency in all these heights is for the female to increase more rapidly in weight from 20 to 50 than do the male. This trend is shown also by the unadjusted weight curves in Table IV.—the actual increase of the female weight for the combined heights being 1.9 pounds more than that of the male.

This period of more rapid increase in weight corresponds to the reproductive period of a woman's

TABLE V

life, which, taken in conjunction with a woman's more sedentary habit, would appear to be a reasonable explanation of the difference shown in the weight curves of the two sexes.

17 West Tenth Street.

IS FOOD CONTAINING BENZOATES INJURIOUS TO HEALTH?

By E. E. SMITH, M.D., PH.D.,

NEW YORK.

PROFESSOR OF PHYSIOLOGY AND ORGANIC AND BIOLOGICAL CHEMISTRY, FORDHAM UNIVERSITY SCHOOL OF MEDICINE. DIRECTOR OF RESEARCH, RED CROSS HOSPITAL.

The Federal Food and Drugs Act of June 30, 1906, provides in section 7, "That for the purpose of this Act an article shall be deemed to be adulterated . . . In the case of food; . . . If it contain any added ingredient which may render such article injurious to health."

Section 3 of the Act provides that the Secretary of the Treasury, the Secretary of Agriculture, and the Secretary of Commerce and Labor shall make rules and regulations for carrying out the provisions of the Act, and acting under this provision the secretaries have, by Regulation 15, delegated to the Secretary of Agriculture the duty of determining the wholesomeness of colors, preservatives, etc. With this end in view, certain investigations have been conducted by the Bureau of Chemistry and are published, in part, in Bulletin No. 84, "Influence of Food Preservatives and Artificial Colors on Digestion and Health."

In discussion at a meeting of the Medical Association of the Greater City of New York (see proceedings, 1907), the writer's attention was called by Dr. H. W. Wiley to the results since published in Part III, "Sulphurous Acid and Sulphites." A reply was made October 16, 1908, at the meeting of the New York Section of the Society of Chemical Industry. A consideration of the data in the Bulletin led the writer to differ so markedly with Dr. Wiley's conclusions that it seems of importance to consider the data in Part IV, "Benzoic Acid and the Benzoates."

The method of investigation was the employment of a class of supposedly healthy men on a constant diet of known composition, the composition of the urine and feces being likewise known from analysis. The time extended over a period of forty days, consisting of two fore subperiods of five days each, four preservation subperiods of five days each, and two after subperiods of five days each. During the four preservative subperiods, benzoic acid was administered to six of the men and sodium benzoate to six. The total amounts (expressed as benzoic acid) varied from 13.5 to 35 grams.

From the "daily medical and clinical notes" of the men and from the metabolic processes as determined by the chemical data above referred to, certain general conclusions were reached. The essential statements of these conclusions are as follows:

"The administration of benzoic acid, either as such or in the form of benzoate of soda, is highly objectionable and produces a very serious disturbance of the metabolic functions, attended with injury to digestion and health."

"This injury manifests itself in a number of different ways, both in the production of unfavorable symptoms and in the disturbance of metabolism. These injurious effects are evident in the medical and clinical data which show grave disturbances of digestion, attended by phenomena which are clearly indicative of irritation, nausea, headache, and in a few cases vomiting. These symptoms were not only well-marked, but were produced upon healthy individuals receiving good and nourishing food and living under proper sanitary conditions."

"It was also noticed that the administration of benzoic acid and benzoate of soda was attended with a distinct loss of weight, indicative of either a disturbance of assimilation or an increased activity of those processes of the body which result in destruction of tissues. The production of a loss of weight in cases of this kind must be regarded as indicative of injurious effects."

"While often the metabolic changes were not strongly marked, such changes as were well established were of an injurious nature. It is evident that the administration of these bodies, therefore, in the food tends to derange metabolism in an injurious way."

"The occurrence of microscopic bodies in the urine is undoubtedly increased under the administration of benzoic acid in both forms, thus showing conclusively the tendency to stimulate the destructive activities of the body."

The conclusion that benzoic acid and benzoates are injurious is, then, based upon the following findings:

(1) Loss of weight. (2) Disturbance of the metabolic functions, as indicated by (*a*) an increased elimination of urinary solids (p. 1289); (*b*) an increased elimination of sulphur (p. 1208); (*c*) an increased elimination of nitrogen (p. 1166). (3) An increase of the microscopic bodies of the urine. (4) Disturbances of digestion, indicated by gastric distress, nausea, and in three cases (p. 1084) vomiting, often attended with headache.

1. Loss of weight. This averaged 1 kilo each with the benzoic acid group and 0.6 kilo each with the sodium benzoate subjects. Before concluding that the loss is due to the action of the preservative administered other possible causes must be excluded. Ordinarily two such causes present themselves for consideration. Increased body work produces this result, as is well known, but the data of the Bulletin afford no reason for believing that this factor was not reasonably well controlled. We may at least assume that it was, since a sufficient increase in physical exercise to reduce body weight would be readily appreciated.

The ingestion of insufficient food is a second cause of reduction of weight, one frequently employed to produce this result. The quantity of food is accurately known from the data of the investigation and, fortunately, we are able to consider this factor with reasonable exactness.

Subject 1, weighing 71.02 kilos, average during the first fore subperiod, weighed 69.41 kilos during the last after subperiod. During the period he ingested a total of 23,523 grams of food solids. Was this sufficient to maintain the body weight? To answer this question we fortunately have for comparison the diet of the same subject during a similar period of forty days which ended a month before the present period began (this Bulletin, Part III, p. 792). Here we find the weight in the first fore subperiod 68.44 kilos, in the last subperiod 68.76, that is, nearly constant, while the subject ingested a total of 26,586 grams of food solids. That is, 13 per cent. more food was ingested to maintain body weight during a former period of

forty days than was ingested during the period under consideration. More than this, we see that the subject had increased in weight to 71.02 kilos during the intervening month. It is clear, then, that what happened is this: The subject was in practical equilibrium during a former forty-day period, he increased in weight during an interval of thirty days when there was no diet restriction, showing therefore an increased ingestion of food during this interval, and then, during the period of forty days of this experiment, ingested 13 per cent. less food than during the former forty-day period, his weight diminishing, though not to the weight in the former period. This diminution is fully explained by the diminished quantity of food ingested and cannot in fairness be connected with the administration of benzoic acid during the period. It was dependent on the restricted diet and would have occurred if benzoic acid had not been administered.

Subject 2, considered on the same lines, shows the same relation of weight to the amount of food ingested. In the former period there was a loss of 1.18 kilos in body weight on 26,428 grams food solids; in the present period a loss of 1.20 kilos on 25,943 grams. The weight is clearly explained by the quantity of food and cannot be attributed to the benzoic acid.

Subject 3 ingested 26,670 grams food and gained 0.88 kilo in the former period; he ingested 25,406 grams, being 5 per cent. less food, and lost 0.55 kilo in the present period, the loss being clearly related to the diminished diet and not attributable to the benzoic acid administered.

Subject 4, did not lose weight during the administration of benzoic acid.

Subject 5 ingested 18,879 grams food and lost 1.99 kilos weight in the former period; he ingested 19,594 grams, being 3.6 per cent. more food, and lost only 1.0 kilos in the present period, the loss corresponding to the quantity of food.

Subject 6 ingested 24,678 grams food and lost 0.44 kilo weight in the former period; he ingested 22,494 grams, being 9.7 per cent. less food, and lost 1.16 kilos weight in the present period, the loss corresponding to the diminished quantity of food.

Subject 7 ingested 13,581 grams food and lost 0.89 kilos weight in the former period; he ingested 12,875 grams, being 5 per cent. less food, and yet lost only 0.67 kilos in the corresponding present period, thus losing less than might be expected from the diminished quantity of food.

Subject 8 ingested 25,900 grams food and gained 0.28 kilo weight in the former period; he ingested 22,942 grams, being 12.9 per cent. less food, and lost 1.99 kilos in the present period, the loss corresponding to the diminished quantity of food.

Subject 9 ingested 19,212 grams food and gained 0.08 kilo in the corresponding former period; he ingested 17,864 grams, being 7.5 per cent. less food, and lost 0.33 kilo in the present period, the loss corresponding to the diminished food ingestion.

Subject 10 did not lose weight during the administration of sodium benzoate.

Subject 11 ingested 29,895 grams of food and gained 0.06 kilo weight in the former period; he ingested 25,649 grams, being 10.5 per cent. less food, and lost 1.78 kilos in the present period, the loss corresponding to the diminished quantity of food ingested.

Subject 12 gained in weight.

There is no exception among these cases. Each clearly shows that any loss of weight is dependent on the quantity of food. There is no reason and no justification for concluding that the benzoic acid and sodium benzoate were in any way factors in the production of loss of body weight. Hence it is equally true that the loss of the body weight may not be "regarded as indicative of injurious effects" as a result of administration of these preservatives.

2. Metabolic Functions. (*a*) Increase of Urinary Solids. The figures show an irregularity in the quantity of urinary solids and in various ways invite comment as to the conclusion reached in the Bulletin. A little calculation shows that the slight increase during the benzoic acid preservative subperiods (see summary, p. 1113) is largely explained by the increase due to the elimination in the urine of the drug itself, as benzoic and hippuric acids (p. 1054-5) and their salts. If due weight is given to this factor, the increased elimination of solids, during the benzoic acid preservative period, is practically accounted for.

With the sodium benzoate subjects, three showed little or no change, one showed a decreased and two an increased elimination of urinary solids, the average of the whole being a small increase. This increase, then, was not general. Further, it is diminished by deducting the benzoate eliminated. If finally the conclusion is justified that on the whole there is a very small increase of urinary solids, it clearly is not attributable to the benzoic element, since, as we have seen, such an increase is not produced by benzoic acid and hence it is to be attributed to the sodium, an entirely innocuous food constituent.

(*b*) Increased Elimination of Sulphur. Since the body was losing weight, it might be assumed that it would lose products of metabolism. As a matter of fact, it was gaining in products of protein metabolism, indicating that the loss in weight was in the metabolism of non-protein body constituents. The gain in sulphur was less during the preservative subperiods and still less during and after subperiods. Interestingly enough, the diminution in the body gain of sulphur began not with the administration of the preservative, but with the second fore subperiod. Why, then, do we attribute the diminished gain to the preservative when it began five days before the preservative was given? Clearly, the figures of the first fore subperiod represent a condition before adjustment of the sulphur balance to the dietary conditions while the subsequent balance, which is nearly constant, was not disturbed, even when the preservative was administered.

(*c*) Increased Elimination of Nitrogen. The nitrogen balance (p. 1181) presents a condition similar to the sulphur figures. The second fore subperiod shows an increase in retention of nitrogen; the other subperiods, including those when preservative was administered, are nearly constant. If there was a disturbed metabolism, by what right do we conclude that it occurred in the three preservative subperiods which agree closely with the other three control subperiods and that the fault was not in the second fore subperiod? All the facts force us to conclude that the evidence does not establish any action of the preservative on the nitrogenous metabolism.

3. An Increase of the Microscopic Bodies of the Urine. Under this head are grouped all bodies appearing in the sediment. Their origin and significance are quite different in the case of the individual bodies, yet they are considered as a

whole. So far as the data furnish any clew to the meaning of their increase, they suggest that the crystalline elements have separated from solution because of the increased urinary acidity, which is a well-known result of the administration of benzoic acid and its compounds, and that the acid urine has acted on the urinary tract so as to increase the elimination of the morphological elements. There is no evidence in the increase of microscopic bodies of any general "tendency to stimulate the destructive activities of the body."

4. Disturbances of Digestion. A study of the "clinical data" reveals a most astounding condition. Two of the subjects developed elevation of temperature in the fore subperiods (regarded as an irrelevant circumstance) and six during the preservation after subperiods. Moreover, five subjects complained of colds (one without elevated temperature), four of whom had sore throats. Thus nine of the twelve men admittedly suffered from affections presumably all of the upper respiratory passages. There is no record in the clinical data of a single throat examination, and no mention of the fact of these illnesses in the conclusions, yet the conclusions do state regarding the effects of the benzoic acid and benzoates: "These injurious effects are evident in the medical and clinical data which show grave disturbances of digestion, attended by phenomena which are clearly indicative of irritation, nausea, headache, and in a few cases vomiting. These symptoms were not only well-marked, but were produced upon healthy individuals receiving good and nourishing food and living under proper sanitary conditions." In the conclusion (p. 1084) mention is made of the fact that three men vomited, yet attention is not called to the fact that two other men vomited, one four days and the other ten days after the discontinuance of the preservative. Moreover, with the occurrence of digestive disturbance no mention is made of the appearance of the tongue, the first point of inquiry by the practical clinician; nor was the vomit examined for what light it might throw on the gastric condition.

Of the three men not mentioned in the above, No. 12 was ill with measles just before the beginning of the experiment. To what extent pain in the stomach and headache during the preservative subperiods are dependent on that fact is uncertain, but the relation of the symptoms to the preservative is at least doubtful, since nausea and weakness are recorded as again coming on the twelfth day after the discontinuance of the preservative. No. 7 also developed nausea, but the pulse of 90 suggests that he may have been participating in the endemic of coryza which affected the class.

No. 1 alone seems to have been free from evidence of any illness, and it so happens that he also failed to record any symptoms attributable to the preservative administered, notwithstanding the fact that he received the maximum amount. The deficit is very ably supplied by the writer of the Bulletin in the following sentence (p. 1063): "There were no symptoms during the preservative period which the subject thought worthy to be recorded at the time; but he mentioned on several different occasions that, although he did not suffer from acute pains, he noticed a gradual decline in strength and a general physical weakness, so at times he was scarcely able to attend to his work." It repays one to dwell upon this statement. Although he suffered from a general physical weakness, so that at times he was scarcely able to attend to his work, it was not a symptom which he thought worthy to be recorded at a time when symptoms were at a premium. Such a statement is best submitted to the jury for their verdict without comment.

To summarize:

1. The loss of weight was not evidence of an injurious action of the preservative administered since it was because of a diet insufficient to maintain body weight.

2. The disturbances of metabolic functions, as evidenced by a supposed increased elimination of metabolic products, did not show any injurious action of the preservative administered, since no real increase was produced, excepting only the increase of urinary solids which was largely due to the elimination of the benzoic acid and its products.

3. The increase of microscopic bodies of the urine did not show any general tendency to stimulate the destructive activities of the body, and hence is not indicative of an injurious action of the preservative.

4. The disturbances in digestion cannot be attributed to the action of the preservative, since the subjects were not in a healthy condition, but were suffering from acute coryza and sore throats with the accompanying fever, which conditions are themselves, as is well known, a cause of gastric disturbances.

In conclusion, then, the evidence presented in Bulletin 84, Part IV, does not establish any injurious effect of benzoic acid and benzoates, even in the quantities and manner administered.

A MODIFIED BOWLES STETHOSCOPE.

By GEORGE MANHEIMER, M.D.,

NEW YORK.

The accompanying illustration shows a slight modification of the Bowles stethoscope. It is an ordinary binaural stethoscope with a Bloomfield plug

and a Bowles chestpiece. Only in the latter the metal rim is replaced by one of hard rubber, thereby avoiding the sensation of cold at first contact felt by the patient, especially in cold weather.

60 East Fifty-eighth Street.

Bier's Method in Dermatology.—Taylor and McKenna have recently devised several forms of Bier's vacuum apparatus for use in dermatology and have employed them with most advantage in cases of lupus, acne, furunculosis, various forms of odematous eczema, and leg ulcers. They had found a negative pressure of 2½ lbs. per square inch, sufficient to produce a copious discharge of serum from callous ulcers, being the treatment followed by the rapid formation of healthy granulations. Edematous eczemas drained in the same way rapidly healed up, and the vacuum process applied in cases of lupus, while of great value in itself, was of special efficacy when used in conjunction with the Finsen lamp. The method flushed the tissues from within, and by bringing serum laden with opsonins to the seat of the disease aided phagocytosis.—*The Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 2, 1909.

INSANITY IN THE SIXTH AND SEVENTH DECADES.

OLD AGE has for long shared with malaria, and recently with autointoxication, the distinction of being a sort of etiological catch-all, any morbid condition occurring in one over sixty, the cause of which is not patent to the laziest diagnostician, being blithely referred to arteriosclerosis or other assumed senile changes. Arteriosclerosis, however, is now known to be a disease of those who live fast, as well as, or rather than, of those who live long, and gradually one disease after another, formerly regarded as of old age is being discovered to be simply in old age. In psychiatry especially, perhaps, the senility theory has been found most convenient and satisfactory, any form of insanity occurring in persons past the meridian of life being often looked upon as due purely to the age of the subject, and therefore, the cause being irremediable, being regarded as itself incurable.

Recently Drs. E. E. Southard and H. W. Mitchell have studied twenty-three cases of mental disease developing in the sixth and seventh decades in order to determine their relation to senile phenomena. All those cases came to autopsy and consequently the clinical analysis was supplemented by a study of the anatomical changes. The report of their findings was presented to the American Medico-Psychological Association at its annual meeting in Cincinnati in May, 1908 (*American Journal of Insanity*, October, 1908). Of those twenty-three cases, three were alcoholic in origin, five were paranoiac, four were cases of delirium, three were maniacal, and nine were cases of depression. In none of these cases was the insanity characteristically due to the premature onset of senile atrophy of the brain. Atrophy was found in several of the brains examined, and in all the cases in which it occurred the duration of life beyond the onset of mental disease was much longer than in the case of those subjects whose brains were of normal or over weight. The insanity could not therefore be rightfully referred to the atrophy as a cause. The pigmentation also was not characteristic of old age. Perivascular cell pigmentation was a constant feature, but this is a not infrequent feature in normal brains of persons in the fifth decade. The neuroglia cell pigmentation was also constant, but it varied in degree in the different cases, and the significance of the variations was not at all apparent. More striking variations were shown in the nerve cell pigmentation. In four cases there was hardly any pigmentation, in eight only was the senile yellow pigmentation present in the Betz cells. In one case the satellite cells were highly pigmented, while the adjacent nerve-cells were without pigment. On the whole there was little characteristic in the pigmentation, the variations being interesting but without apparent significance in relation to the age of the subjects.

As a result of their studies, clinical and anatomical, of these cases the authors conclude that "neither old age changes nor arterial disease have any necessary connection with the development of insanity in the later years of life, at least in the sixth and seventh decades. It seems probable that arteriosclerosis, senility, and various forms of insanity are entities which frequently interpenetrate, but are logically and genetically quite separate. Even the degree to which old age and arterial disease serve as complicating factors in insanity has been much overestimated."

If Drs. Southard and Mitchell are right in their conclusions, and so far as the findings in those cases go there seems to be no reason to doubt them, one more of the opprobria of old age has been removed. The more disease in the aged is studied, the more "normal," if such a term can be applied to disease, is it found to be; that is to say, the more is it found to be subject to the same etiological laws as disease at other periods of life, and the less is it seen to be due to age *per se*. Doubtless there are degenerative changes coincident with or dependent upon senility, but disease in the aged is by no means always referable to those changes, and the modern investigation of the physiology and pathology of old age is demonstrating every day the fatuity of Cicero's assertion that old age is itself a disease. There is a normal old age in which life is as endurable and as enjoyable as it is in the young or the mature, and the reward of patient and rational treatment of disease at this time is as great as at any other period.

EMASCULATED STIMULANTS.

THAT familiar feature of social life in Anglo-Saxon countries, namely, the crusade for abstinence from alcoholic beverages, has but recently reached Germany, the land where beer is the national drink and the use of tobacco an implied attribute of manhood. The proverbial "thoroughness" of the Germans is, however, once more exemplified in some of the features of the crusade; not only "alcohol-free" drinks have been introduced, but "nicotine-free" cigars and "caffeine-free" coffee are extolled in the medical and general press. It is this last feature of the subject that has called a vigorous expression of opinion from Professor Erich Harnack, who is perhaps best qualified to claim authority in the matter (*Deutsche medizinische Wochenschift*, Nov. 5, 1908). He very pertinently points out the contradiction in terms and ideas in the introduction of "alcohol-free" wines and beers, when the only reason for the use of the latter beverages by the great majority of mankind is their content of alcohol.

Moreover, all inquiries into the use of stimulants must be held with the fact ever in mind that their general popularity among all nations and races is probably founded upon a real requirement of the stimulation derived from them, and self-deception in the shape of substituting similarly sounding names for beverages that do not contain the elements for which real wines and beers are prized will not lead to the general adoption of such drinks as substitutes.

"Caffeine-free" coffee, the latest product of such crusades, especially sins against these considerations; if it contains none of the stimulating properties of coffee, there is very little reason for paying high prices for the "emasculated drink," as Harnack terms it. If it is only poor in caffeine, then it is quite probable that the "slaves of the cup" will use more of it to obtain the same amount of stimulation that they were wont to get from the original drink. If they have enough strength of mind to be satisfied with a smaller amount of the stimulating principle of coffee, then the usual dilution of the drink with milk or water will answer their purpose very well. Such dilution will certainly save their money as well as do away with the very real risk of being gradually injured by the foreign constituents of the "caffeine-free" coffee that may have been introduced during the process of extracting the alkaloid.

That there is room for the use of stimulants, whether alcoholic beverages, coffee, or tobacco, that have been reduced in strength is probably true; gradual omission of such substances must often be carried out with sick persons, and the artificially weakened products may then answer a real need. That it is wrong to carry on any crusades against excessive use of stimulants, or any use of them whatever by young people, by means of unwarranted declarations of the amount of harm caused by them, is equally true. The medical profession, especially, must be careful in lending its support to any such crusade; it may find itself either responsible for statements for which there is no foundation in facts of medical science, or quoted in support of this or that commercial product of the kind that Harnack classifies among the "emasculated" stimulants. The whole question of the crusade for the substitution of these products for wine, coffee, and tobacco forcibly reminds us of a passage in an essay of Professor William James of Harvard. He had for the first time visited the model community of Chautauqua and was deeply impressed with the approach to the ideal of civilized life that he found there, and for a few days it seemed to him as if the great world outside was but a scene of meaningless strife and danger, the return to which after the ideal life of Chautauqua would be a real hardship. But the moment his train left that town he felt the immense relief of having once more entered life that carried with it risks and dangers and temptations, the daily battle with which constituted the real significance of living. The artificial community where ice cream soda was the most intoxicating drink and a debate about music the only safety valve for anger lacked the very elements that made life worth living.

EXAMINATIONS.

A WIDE divergence of opinion exists as to the value of examinations. On one point, however, all are agreed that so far as the entrance to the medical profession is concerned, no system of examination is perfect and that many systems are remarkably faulty and ineffective. Yet, on the whole, it must be conceded that the examination test is necessary, and until some better mode is devised probing the knowledge of the would-be medical practitioner must be continued. This being so, it behooves those responsible for the conduct of medical examinations to see that these tests really fulfill, as far as is possible, the object for which they have been founded. In this country, for example, no one would assert that the system of examination in the various States is best calculated to provide men fully competent to act as medical practitioners even from the standpoint of theory. Examinations in medicine and surgery in different parts of America are not of an equal standard. Great progress in the direction of uniformity has been made during recent years, but still the examination standards for entrance to the medical profession are very unequal.

Examinations in themselves differ widely. Some papers appear to be composed with the sole object of leading the candidate into difficulties. The questions are frequently ambiguous and unaccustomed terms and expressions are used. It need scarcely be said that questions cannot be too straightforward. A paper should not be too long; the questions should be set down in plain, clear language, and the candidate, especially if a practitioner of long standing, should not be expected to have an intimate acquaintance with the most recent methods of laboratory research.

But while the written examination is a sufficiently trying ordeal, the *viva voce* is generally a far more painful experience, and it is in the spoken examination that the qualities of the examiner are most plainly shown. There are some men who are born examiners and others who are exactly the reverse. With the nervous man, and nervousness when being examined by no means implies lack of knowledge, the bad examiner is seen at his worst. He does not try to allay the nervous feeling but almost invariably continues to reduce the unfortunate individual to such a condition that in some instances he scarcely knows his own name. On the other hand, the good examiner will do his best to soothe the candidate's disturbed mental sensations, and by judicious questioning lead him back into a sane state of mind. It must be remembered that an examiner's duty is to find out what a man knows rather than what he does not know and to exercise discrimination. In short, examiners are in need of training for their posts nearly as much as are candidates. Because a man is a skilled surgeon or a distinguished physician it does not follow that he will be a good examiner. For this position a certain aptitude is required, as well as practical experience and some training. Fortunately for the candidate, however, the State Board examinations are written and he is spared the ordeal of thinking

on his feet, with a tired and possibly impatient examiner doing everything possible, even if unwittingly, to confuse him.

Resuscitation.

Two years ago Crile and Dolley excited the interest of the medical profession by publishing the results of their resuscitation experiments. They killed animals by means of anesthesia or asphyxia and having allowed the heart to remain still for periods of time varying from a few seconds to thirty-five minutes, brought them back to life by centripetal injections of salt solution to which adrenalin chloride was added. The cessation of heart function resulted, of course, in anemia of the body organs and it could be supposed that although the heart could be made to beat once more irreparable injury may have been done in the meantime to more delicate structures, such as the components of the nervous system. Recently the same authors have investigated this phase of experimental resuscitation and have published the results in the *Journal of Experimental Medicine*, Volume 10, No. 6. A series of thirty dogs were killed by chloroform and then resuscitated according to the above method. If the resuscitation occurred within five minutes of the death of the animal the recovery of function was very rapid and quite complete, showing that the injury done to the nerve cells by the complete anemia during that period was not very intense. Death for a period of over seven minutes seemed to have led to very grave changes so far as function is concerned, for only one dog of the twelve in this series recovered. Histological examination corroborated the functional results; the nerve cells of the fatal cases presented changes indicative of chromatolysis and even of cell death, while special methods of staining proved the existence of fiber-degeneration as well. The authors conclude that six or seven minutes is the average limit of total cerebral anemia which admits of recovery under conditions similar to the circumstances surrounding their experiments. As sudden death from asphyxia or from the effects of anesthesia is the most frequent accident which in human beings may call for the employment of such methods of resuscitation, the determination of the experimental limit of possible recovery is of course of great importance in connection with attempts in this direction.

News of the Week.

Various Occurrences at the Tuberculosis Exhibition.—Physicians and others from many parts of the State came to New York on December 21, to attend the Tuberculosis Exhibition at the American Museum of Natural History. Addresses were made by Mr. Joseph H. Choate, who presided at the evening meeting, the Right Rev. Richard H. Nelson, Health Commissioner Porter, and Dr. Hermann M. Biggs. Dr. Biggs outlined a plan for the State control of the disease, providing for the erection of sanatoria for the care of tuberculous patients, the cost of each patient to be charged to the county from which he comes, and for State aid for small towns and communities wishing to erect sanatoria of their own. He suggested that the State might agree to subsidize such local sanatoria to the amount of $500 a bed, since the care of the tuberculous was certainly as much to the State as the care of the insane. He thought the carrying out of the suggestions would lower the death rate in the State almost fifty per cent. It was estimated that about eight thousand persons attended the day's meetings.

A thousand Italians of all sorts and degrees attended the special Italian night at the Tuberculosis Exhibition on December 26. Dr. Antonio Stella, Consul General Massiglia, and Mr. Ernesto Fabbri addressed the meeting.

Sunday, December 27, was the Hebrew day, and the occasion brought a total of 63,112 visitors, the largest crowd that ever gathered in one day in the Natural History Museum. The exhibition has been widely advertised for weeks in the lower east side, and Jewish day was particularly well advertised. When the doors were opened at 1 o'clock the lines of waiting people ran back for a block or so from the Seventy-seventh street entrance and for three or four blocks from the Seventy-ninth street entrance. The usual afternoon program was given in Yiddish, and when one audience had been talked to it was moved out and another one marched in. In spite of the unprecedented numbers, there was no disturbance or disorder.

Cost of Mosquito Extermination.—Dr. John B. Smith, the New Jersey State Entomologist, in his annual report to the Governor says that municipalities are now cooperating with the State in the extinction of the mosquito, and that the time is drawing near when there will not be a mosquito left in New Jersey. The total appropriation for the work for the year was $20,000, of which only $15,458 was used, leaving a balance of $4,542. There were 17,620 acres of marsh land drained, and 2,394,174 feet of ditches were built to keep stagnant water from collecting in breeding places. It is said that the draining of the marshes about Jersey City have caused the complete disappearance of the mosquitos from that region.

Union of Medical Schools.—By the absorption of Hamline College, the last of the private medical schools in Minnesota, by the State University, Minnesota becomes one of the two States in the Union where the teaching of medicine is entirely in the hands of the State universities and is controlled altogether by the State authorities. The same condition of affairs prevails in Vermont. When the Department of Medicine was established in the University of Minnesota some years ago, four private schools for teaching medicine were in existence; the State Medical College at St. Paul, the Minnesota Hospital College, the Minnesota College of Homeopathic Medicine, and the College of Physicians and Surgeons, at Minneapolis. The last was later affiliated with Hamline University, but the first three surrendered their charters and united with the State University. A meeting to celebrate this unification of medical teaching was held on December 8, in the University chapel, and was attended by the students, the alumni, and members of the medical profession.

A School of Preventive Medicine.—Columbia University, New York, has for some time had under consideration the possibility and practicability of establishing a thoroughly organized school or department of Hygiene, Sanitary Science, and Preventive Medicine, and recently a committee consisting of officers of the University has been appointed to study the subject and to report thereon. The committee is composed of Dr. N. E. Ditman, Chair-

man, Dean Samuel W. Lambert, Profs. M. Allen Starr, F. S. Lee, Edward T. Devine, Livingston Farrand, E. R. A. Seligman, G. N. Calkins, W. H. Burr, Dean F. A. Goetze, and Dr. Rudolf Tombo, Jr.

New York's Death Rate.—During the week ending December 19, there were in New York City 1,359 deaths, representing a rate of 16.03. While these figures show an increase over the figures for the previous week, they are lower than those for the same week of 1907, when the total number of deaths was 1,711 and the rate was estimated at 20.83. One hundred and eighty-five deaths from tuberculosis occurred during the week.

Cholera in St. Petersburg.—A fresh outbreak of cholera in St. Petersburg accompanied a cold wave there toward the end of December. Thirty-one new cases were reported on December 25, and thirteen deaths, making a total of 225 persons in the hospitals suffering from the disease.

Smallpox in Philadelphia.—A case of smallpox has been discovered in a colored woman in Philadelphia who had come from Carolina County, Va. The patient was sent to the Municipal Hospital and the neighborhood was quarantined while all of those in the infected zone were vaccinated.

Scarlet Fever Epidemic.—Because of an epidemic of scarlet fever in Warsaw, Ind., the municipal authorities have closed the schools, and have refused to allow any public Christmas entertainments.

Expensive Leper Dead.—Mock Sem, a leper who has been the charge of the City of Harrisburg, Penn., since July, 1907, died on December 25, at the Municipal Hospital. He came from China, and while working in a restaurant as a cook was found to be suffering from the disease and was isolated. American cooking did not please him, and it was found necessary to supply him with a stove and the raw materials with which to prepare his own meals. The cost of his maintenance was about $175 a month, which caused many debates in the City Council.

Isolation Ward Closed.—The Managers of the Mountainside Hospital at Montclair, New Jersey, announce that hereafter the isolation ward of that institution will be closed, because of the opening of the new isolation hospital at Soho, which permits of better care of contagious patients.

The Red Cross Hospital, New York, has acquired the lot on the southwest corner of Central Park West and One Hundredth street adjoining its present building. It is understood that the hospital facilities will soon be considerably increased.

Marine Hospital at Pittsburg.—The cornerstone of the new Marine Hospital at Pittsburg, Pa., was laid on December 23, the ceremonies being conducted by Harbor No. 25, Master and Pilots, American Association. The building is situated in a portion of the former Arsenal grounds which was reserved when the United States made a lease to the city of Pittsburg of the present Arsenal Park. The former Marine Hospital was discontinued twenty-five years ago, and the sick and injured members of the Association have since that time been cared for at Mercy Hospital under the contract system. There are thirty-eight firms and steamboat owners operating out of Pittsburg, and when the rivers are at a boating stage they employ 2,600 officers and men. Twenty-five thousand dollars has been appropriated for the structure.

Charitable Bequests.—By the will of the late Dr. William J. Earheart of Philadelphia the sum of $5,000 is bequeathed to each of the following institutions for the endowment of a free bed: Women's Homeopathic Hospital, Children's Homeopathic Hospital, Hahnemann Hospital, Women's Southern Homeopathic Hospital, and St. Luke's Homeopathic Hospital. By the will of the late Mrs. Sarah E. Kolb, the sum of $5,000 each is bequeathed to the German Hospital and the Home for Incurables, for the endowment of a free bed, and $1,000 is left to the German Protestant Home.

The Chicago Milk Commission, through its Secretary, Dr. A. Belcham Keyes, has issued a physician's order blank on the back of which is a list of stock formulæ of milk for infants, and a list of the milk stations where the milk may be obtained. The Commission has also issued leaflets on "buttermilk food for infant feeding," and how to take care of the baby.

Newspaper Publicity Unethical.—The Madison County Medical Society (Ill.) recently adopted resolutions deploring the practice of newspaper publicity on the part of members of the medical profession, on the ground that it is foreign to the principles and ethics of the medical profession, and requesting the publishers of newspapers to omit the names of physicians and of their deeds from the columns. The publishers and editors of newspapers will probably continue to publish the news.

The New York Herter Lectures.—Professor J. B. Leathes, of the Lister Institute of Preventive Medicine of London, England, will deliver six lectures on "The Metabolism of the Non-nitrogenous Substances in the Animal Body" in the Carnegie Laboratory of the University and Bellevue Hospital Medical College, beginning on Monday, January 4, and continuing daily throughout the week, at four o'clock in the afternoon. All those interested are cordially invited to attend the course of lectures.

The Washington County (Me.) Medical Society held its annual meeting at Calais on December 10, when the following officers were elected for the ensuing year: Dr. E. H. Bennet of Lubec, *President;* Dr. F. N. Shaw of Machias, *Vice-President;* Dr. F. W. Russell of Robbinston, *Treasurer;* *Board of Censors,* Drs. Deacon of Milltown, N. B., Waller of Milbridge, Webber of Calais.

The Minneapolis Homeopathic Society, at its regular meeting on December 15, elected the following officers: *President,* R. D. Matchan; *Vice-President,* A. G. Hammond; *Secretary-Treasurer,* J. D. Wallen.

The San Bernardino County (Cal.) Medical Society held its annual meeting on December 10 and elected the following officers: *President,* W. P. Burke of Highland; *First Vice-President,* Hoell Tyler, Redlands; *Second Vice-President,* T. M. Blythe, Redlands; *Secretary,* G. G. Moseley, Redlands; *Treasurer,* William A. Taltavall, Redlands. D. C. Strong of San Bernardino was elected delegate to the State meeting at San José in April.

The Northwestern Ohio Medical Association closed a two-days session in Findlay on December 12, by the election of the following officers for the ensuing year: *President,* Dr. Thomas Hubbard of Toledo; *Vice-Presidents,* Dr. Charles Mertz of Toledo, and Dr. O. L. Norris of Deshler; *Secretary,* Dr. E. A. Murbach of Archbold; and *Treasurer,* Dr. S. T. Elmore.

The Schoharie County (N. Y.) Medical Society held its annual meeting on December 8, at Cobleskill. The following officers were elected: *President,* C. S. Best, Middleburg; *Vice-President,* E. E. Braman, Livingstonville; *Secretary,* C. L. Olendorf; *Treasurer,* L. R. Becker; *Censor,* W. T. Rivenburg. Joseph R. Brown of Seward was chosen delegate to the meeting of the State society which convenes in Albany the latter part of January.

The Delaware County (Ia.) Medical Society, at its regular quarterly meeting in Manchester on December 9, elected the following officers: *President,* Dr. Hugh Livingston, Hopkinton; *Vice-President,* Dr. H. A. Dittmer, Manchester; *Secretary and Treasurer,* L. J. Bowman, Manchester; *Delegate to State Meeting,* Dr. C. B. Rogers of Earlville.

The Greene County (Mo.) Medical Society held its annual business meeting in Springfield on December 11. The following officers were elected to serve for the ensuing year: *President,* Dr. F. B. Fuson; *Vice-President,* Dr. C. E. Woody; *Secretary,* Dr. J. E. Dewey; *Treasurer,* Dr. D. B. Farnsworth; *Censor,* Dr. N. F. Terry; *Delegate to State Medical Association* at Jefferson City in May, Dr. W. M. Smith; *Alternate Delegate,* Dr. J. R. Boyd.

Rabies on the Isthmus.—There have been a number of cases of hydrophobia in the Canal Zone recently, and several persons bitten by supposedly mad dogs have come to Washington to receive preventive inoculations. The latest of these arrivals was Dr. Tomasselli of the sanitary department.

The American Roentgen-Ray Society.—The ninth annual convention of this society was held in New York on December 28, 29, and 30, at the Academy of Medicine. In addition, an interesting exhibit of *x*-ray apparatus was on view in the Engineers' Society building.

Obituary Notes.—Dr. Edward M. Tucker of Derry, N. H., died at his home on December 8, aged 68 years. Dr. Tucker began his medical studies under Dr. L. G. Hill of Dover, but at the outbreak of the Civil War he enlisted in the Massachusetts Light Artillery. After being wounded he was discharged for disability in 1862, but was able to reenlist in 1864, and served until the close of the war, when he was appointed a hospital steward in the regular army. He graduated from the medical department of Bowdoin College in 1872, and had practised his profession in Canaan, N. H., until a year ago.

Dr. Charles Allen of Washington, D. C., died suddenly on December 25, after a stroke of apoplexy, aged 73 years. Dr. Allen was a graduate of the Georgetown Medical School, and since his graduation had practised continuously in the District of Columbia until the day of his death.

Dr. James Samuel Clark of Westfield, Mass., died at his home on December 21, after a long illness. Dr. Clark was born in Bellows Falls, Vermont, in 1854, and after a few years of business life entered the College of Physicians and Surgeons, New York, from which he was graduated in 1881. He was a member of the Springfield Academy of Medicine.

Dr. Frederick E. Maxcy of Washington, D. C., died suddenly at his home on December 25. Dr. Maxcy was born in Maine in 1873, and was a graduate of Bowdoin College.

Dr. Richard A. F. Penrose of Philadelphia, father of United States Senator Penrose, died at his home on December 26 of pneumonia, aged 82 years. Dr. Penrose was graduated from Dickinson College in 1846, and three years later received the degree of M.D. from the University of Pennsylvania. He served for three years as resident physician in the Pennsylvania Hospital and later became physician to the Southern Home for Destitute Children. He was Lecturer on Obstetrics and Diseases of Women and Children in the Philadelphia Hospital from 1854 to 1857 and from 1858 to 1859, and Obstetrician from 1859 to 1867. In 1893 he was appointed to the Chair of Obstetrics and Diseases of Women and Children in the University of Pennsylvania, holding this position until 1889. During the Civil War he was one of the surgeons to the Satterlee Hospital, one of the largest army hospitals in Philadelphia. He was one of the founders of the Children's Hospital, of the University Hospital, and of the Cynecean Hospital. He was largely instrumental in opening the wards of the Pennsylvania Hospital to medical instruction. In 1872 Dickinson College conferred on him the degree of LL.D.

Correspondence.

MISLEADING ANTIVIVISECTION LITERATURE.

To the Editor of the Medical Record:

Sir:—Last winter two decided efforts were made before the Legislature of this State by two separate organizations to secure the enactment of laws seriously restricting animal experimentation as a means of established scientific medical progress. It appears that these efforts will be repeated during the coming session of the Legislature. On November 11, 1908, a concert was given in this city by the New York Antivivisection Society for the purpose of advancing their aims in this respect. A pamphlet is now being circulated among physicians and others in various parts of the State by the Society for the Prevention of Abuse in Animal Experimentation, calling attention to the assumed horrors of vivisection, and urging support in the effort which the society will make at the coming session of the Legislature to secure restrictive legislation. This pamphlet is a typical piece of antivivisection literature, and is evidently the work of one whose eyes are shut to the real state of facts, for the recitals made therein are unjustified assumptions and allegations unsupported by proof. They are based largely upon obsolete European exhibitions, and also upon what those who are familiar with progressive science declare to be as ancient history—that is, a history of a period in the development of medical research, the methods of of which are no longer employed by anyone. The misstatements, and fallacious arguments put forth last year are again being restated, notwithstanding the faithless aspect which they then presented. Why do people who claim to present "a fairminded and unbiased view" rehearse misleading things over and over again when they can easily inform themselves of existing conditions? Those who are familiar with modern scientific attainment and practices have no knowledge, nor do they believe, that needless suffering is inflicted in animal experimentation in laboratories or elsewhere; nor has reliable evidence thereof been brought to light by the opponents of vivisection. Eminent legal authorities assure us that the law as it exists to-day in the State of New York is sufficient to punish all, if there be such, who are guilty of cruelties in animal experimentation.

If restrictive laws pertaining to this subject are introduced into the Legislature this winter, the Medical Society of the State of New York will oppose them. In the meantime we would urge the public to refrain from accepting as true such a misleading picture as is presented in the pamphlet above referred to. The Medical Society of the State of New York is prepared to furnish literature expressing the truth regarding animal experimentation and also to furnish speakers for clubs and societies that are interested in this subject.

Frank Van Fleet, M.D.,
Chairman, Committee on Legislation, Medical Society of the State of New York.

APPENDICITIS AND RHEUMATISM.

To the Editor of the Medical Record:

Sir:—Apropos of Dr. Beverley Robinson's communication in the Medical Record for December 19, 1908, commenting upon Dr. Eustace Smith's "Remarks on the Rheumatic Origin of Certain Serous Inflammations," please allow me to say that we need have little discussion over the subject. Rheumatism precipitates attacks of appendicitis, and appendicitis precipitates attacks of rheumatism. According to a theory which was presented in the year 1895, appendicitis follows any cause which makes the soft inner coats of the appendix swell to the point of compression anemia within the narrow and tight outer sheath. Bacteria of the bowel then pounce upon the anemic area which is down. Rheumatic swelling of the lymphoid layer of the appendix often gives the bacteria this chance. The presence of a concretion, extension of ordinary colitis swelling, psoas traumatism—all of these do the same thing. The question of the hole by which the mouse got into the cheese is a quibble. The mouse is at the cheese. That is enough. On the other hand, functional derangement of the bowel, due to the influence of a percussion cap on the nipple of the cecum, can shake down an impending attack of rheumatism. The whole question centers upon the point of presence or absence of infection of the appendix. I have refused to operate in cases of rheumatic inflammation of the appendix, without infection, sometimes to the amazement and dismay of the patient, who promptly called another doctor. No case of infection of the appendix has gone abroad for relief, however.

Robert T. Morris, M.D.

616 Madison Avenue, New York.

HYPOCHLORIDIZATION IN THE TREATMENT OF EXOPHTHALMIC GOITER.

To the Editor of the Medical Record:

Sir:—The administration of bromide in cases of epilepsy with a refusal of sodium chloride having given good results, similar treatment of cases of Graves' disease by bromide of strontium and hypochloridization came to mind. The treatment in full consisted of infusion of digitalis, strontium bromide, potassium nitrite, and a saltless diet. After two weeks of this, the tremor and feeling of nervousness and thrill entirely disappeared, so that a glass of water was quite steady in the outstretched hand, and the patient became tranquil in mind and body. Some digestive symptoms occurred, anorexia and nausea, but these yielded to ordinary therapeutics. The pulse rate fell from 128 to 96. Reports of cases of similar treatment would be appreciated. T. H. Evans, M.D.

Freeport, Long Island.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HEALTH OF THE KING—BRADSHAW SURGICAL LECTURE—USE AND ABUSE OF THE CURETTE—ROYAL SOCIETY OF MEDICINE—CHILDREN'S DISEASES—THE TSETSE AND THE BUFFALO—OBITUARY.

London, December 11, 1908.

The King is practically convalescent—that is, in brief, the news of to-day. His Majesty had a severe cold—slight enough at first, it is said—and he left Windsor and went to Sandringham with it. There it declared itself as influenza and with that neuralgia, keeping him in his room three or four days. On Tuesday he was well enough to go to the seaside for a change and has steadily improved. The deep interest expressed on every side in the King's health shows how entirely he has secured the loyal regard of all his subjects.

The Bradshaw Lecture at the Royal College of Surgeons this year was delivered on Thursday afternoon by Sir W. Watson Cheyne of King's College Hospital. Having served as house surgeon under Lord Lister and consistently followed his practice, he naturally chose as his subject "The Treatment of Wounds" and made a good defense of antiseptics used with judgment as against the more elaborate precautions of those who endeavor to insure absolute asepticism. The president, Mr. Henry Morris, occupied the chair and for the first time the members of Council appeared in their academic gowns. I hope they enjoyed wearing their newly assumed assertion of university rank and felt as self-conscious as they looked, but I cannot see how a self-constituted claim to a new cut of clothes can increase the dignity of surgical science. The lecturer said that in such a science as theirs, where knowledge is still very imperfect, there is considerable oscillation in the current views which prevail from time to time—a constant swinging of the pendulum, so to say, between the opposite points of medical opinion. At the present time, he thought, this oscillation was nowhere more marked than in the views founded on experimental and chemical pathology and perhaps most especially in connection with bacteriology and the relation of bacteria to the living body. The treatment of wounds was just now a subject on which professional opinion was in one of those extreme oscillations. It was not, therefore, his intention to produce new facts, but rather to go over the elementary points of the subject and to indicate to what extent our original conceptions have been modified and how far it is desirable to go according to the present state of our knowledge. Sir Watson Cheyne proceeded to deal in considerable detail with the action of antiseptics, the manner of invasion of bacteria, sterilization, and allied questions. After reviewing these in their various aspects, he summed up his criticisms on the most recent ideas of treating wounds by expressing the opinion that the pendulum had swung too far in the direction of asepticism and the disregard or even avoidance of antiseptics. He held that the reasonable use of all means at our disposal to prevent septic infection of wounds would furnish the most constant results; the attempt to treat them without any antiseptics at all was to exclude a most valuable aid and lead to a number of unnecessary complications. Comparing his own results and those of surgeons who followed the same practice, he held that they were in every way as good as those which had been obtained with the most elaborate devices for securing perfect asepticism; in fact, he ventured to declare they were better because they were more constant, more dependable.

"The Use and Abuse of the Curette" formed the subject of a lecture at the Polyclinic by Dr. Herman, and many will be disposed to say of it "a word in season, how good it is." There is no doubt that it is time to call a halt in the pace of some gynecologists, and Dr. Herman, with his enormous experience at the London Hospital, is well qualified to call it, and I congratulate him on the firmness, courage, and courtesy with which he has spoken. He first pointed out that to curette, or, to use the English word, to "scrape," the uterus when it gave no sign of disease was unjustifiable, although the patient was anesthetised for another purpose. To admit such a practice would lead to operations on healthy people. Disinfecting prior to removing suppurated tubes is unnecessary and also injurious, for it prolongs the anesthesia. For years gynecologists have been talking about endometritis (hyperplastic and polypous). These morbid conditions are adenomatous growths, with no evidence of inflammation, and in them Dr. Herman admitted scraping away the overgrowth in the first instance was good practice. Scraping the uterus in virgins who have no excessive hemorrhage, as had been advised by some, was, in the lecturer's opinion, an abuse, and the same judgment was pronounced on scraping and packing for pelvic pain. Turning to chronic metritis and endometritis, referring to recent papers and discussions, the lecturer held that scraping a uterus which has been infected with pathogenic microbes with the idea of scraping away the whole of the infected tissue was not justifiable, for it was impossible to effect complete removal, and if we could do it we could not know that we had. Again, scraping neurasthenics for pain without excessive hemorrhage could not be defended, even if the pain were supposed to be due to endometritis brought on by variations in the size or shape of the uterus. Such variations have never been shown to be pathological any more than differences in the size of the lobule of the ear.

When a scraper is really required the lecturer preferred a blunt, rigid instrument, which would not cause excessive bleeding and enabled the operator to judge its whereabouts and the force he was applying. The proper use of the instrument was to remove overgrowths. When hemorrhage is so profuse as to weaken the patient and bimanual examination sheds no light on the case, dilatation of the cervix and exploration with the finger would be proper. If nothing is felt, scraping and microscopic examination of the scrapings should follow. Further indications of the

proper use of the scraper were considered by the lecturer, but it is not my intention to follow up this part of his subject, as I regard the question of the abuse of the instrument as far more important at the present time and as demanding the attention of all gynecologists.

The Royal Society of Medicine held its first anniversary dinner on Friday, a number of distinguished guests being present. The toast of the society was given by Mr. Birrell, who, notwithstanding the odium he has earned as Chief Secretary for Ireland, talks as pleasantly as ever on any or every topic. On this occasion he said there was no profession for which he had a profounder admiration and none of which he knew less. Then he told a story of how once he fancied he was smitten with a mortal disease and determined to die *secundum artem*, as he was the last man to be irregular in his departure from the world. So, walking to a specialist's for that disease, he fell into a profound perspiration and while waiting took up a book in which he read "the patient suffering from this disease never perspires," whereupon he picked up his hat and gloves, walked out, and had never seen that eminent specialist from that day to this. The appreciative laugh of the guests having subsided, the president, Sir William Church, responded, of course, in a more serious vein. He told how the society, though still in the infancy of the amalgamation, was doing well, and he thought its success was certain. During the past year they had had a large accession of Fellows and now numbered 2,215. Their object was the advancement and dissemination of knowledge, the means being sectional meetings for the departments of medical science, their proceedings, and their fine library of 100,000 volumes. Some special branches of medicine were at present unrepresented in their body, but he hoped they would ere long be embraced. They were not the Royal Society of Medicine of London, but of the United Kingdom, and indeed of the British Empire. About 1,780 Fellows resided in London, 1,170 in the province, and 220 were scattered over the globe.

The Society for Studying Children's Diseases is now a section of the Royal, and a number of interesting cases were brought forward at the November meeting. Dr. C. E. Finny described one of duodenal ulcer ending in perforation, and showed the specimen. On this Dr. Cantley remarked that though such ulcers gave rise to spasm of the pylorus, which was constricted after death, it does not seem to cause hypertrophy. There is, too, a striking absence of evidence of pain.

Mr. H. M. Rigby showed a case of ectopic vesical in which the ureters had been implanted into the rectum and the child could control the passage of urine. He was congratulated by Mr. Leet, who referred to a number of unsuccessful cases and mentioned one in which the ureters had been implanted into the sigmoid, which became kinked and the issue was fatal. Dr. Sutherland showed a boy with enlarged liver and spleen, for which mercury had been given. Dr. Cantley suggested that the rapid improvement under the drug suggested syphilis, or possibly the child had had peritonitis or tuberculosis. He hoped the exhibitor would keep the case under observation and report, as true atrophic cirrhosis was rare in children. Dr. Spriggs commented on the importance of a nodular state of the liver and thought the spleen not larger than it may be seen sometimes in tuberculous peritonitis.

Dr. Sutherland replied and held to the diagnosis of atrophic cirrhosis. The onset was sudden, with pain and distention, no pyrexia, and he had felt nodules when there was less fluid in the abdomen than now. He did not think there was evidence of syphilis.

The African Society entertained Mr. F. C. Selous on Wednesday. The eminent explorer and big game hunter gave a thrilling account of some of his experiences and incidentally indicated his conviction of an intimate connection between the tsetse fly and buffaloes. He had noticed in his long periods in Africa that wherever the buffalo ceased to roam there the tsetse became extinct, although other big game might remain. The fact that the buffalo is slow of movement and congregates in great herds near the rivers might have led the fly to depend on it almost entirely. Be that as it may, wherever the herds were decimated by rinderpest the fly was brought to the verge of extinction in a few months. Where the tsetse could feed only on the blood of other mammalians, it was found to be innocuous to domestic animals.

Dr. Charles Edward Beevor, the distinguished neurologist, who was at the Royal College of Medicine's dinner on the 4th inst., died quite suddenly on the 5th inst., aged 54. He was the elder son of the late Charles Beevor, F.R.C.S. He took his M.D. Lond. in 1881 and became F.R.C.P. in 1888. He was for a time assistant physician at his own hospital (University College), but became physician to the Hospital for Paralysis and Epilepsy and to the Royal National Orthopedic Hospital. He wrote the articles on diseases of the nervous system in Fowler's "Dictionary of Medicine" and in Allbutt's "System" and contributed to the Royal and other societies, as well as to *Brain* and other medical journals, on various questions connected with neurology. He delivered the Croonian Lectures at the Royal College of Physicians in 1903 and only last year was president of the Neurological Society and gave the Lettsonian Lectures of the Medical Society of London.

Dr. F. Pritchard Davies, for many years physician to the Kent Asylum and formerly connected with Broadmoor, has died at the age of 64. He had been president of the Edinburgh Medical Society and served in other offices. He took M.R.C.S. in 1869 and M.D. Edin. 1879. He contributed articles on his specialty to the *Journal of Mental Science* and the *American Journal of Insanity*, 1877 to 1887.

Dr. Samuel Griffith, M.D., died on the 1st inst., aged 74, at Portmadoc, where he spent his professional life. He took a part for many years in educational and other questions connected with social advance and the prosperity of his town and district.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

EHRLICH'S ADDRESS—EXPERIMENTAL THERAPEUTICS—ACTION OF ARSENIC COMPOUNDS UPON TRYPANOSOMES—DEATH OF ALTHOFF.

BERLIN, December 1, 1908.

THE physicians of Berlin were obliged to pay a visit to quite an unusual place for them in order to hear Paul Ehrlich lecture on "Experimental Therapy." He spoke on this subject before the German Chemical Society, and not only the medical profession was well represented, but all other scientific professions had their best-known members among the audience that greeted the lecturer.

He spoke in the beginning of his lecture of the times when Germany had pharmacological institutes only in which theoretical questions constituted the main part of the work. Even though the development of some practically important drugs was due to the work in these institutes, as, for example, the anesthetics, yet the greatest number of remedies used in medicine was originated by chemists. These remedies were then turned over to physicians for clinical study and the result was mere empiricism in bringing out new drugs. This was the condition of affairs until very recent times when the new institutes for experimental therapeutics appeared and exactly fitted in the place and work that were left unoccupied and undone in the old order of things. Pharmacology stands in the same relation to experimental therapy as anatomy and physiology to the pathological anatomy. It is not enough simply to inject every new remedy into the bodies of animals; in order to obtain more valuable data of the action of the remedy the animal must be sick or be made sick before the drug is tested upon it.

Ehrlich's own studies in the field of experimental therapeutics began with the question of staining *intra vitam*. It was noted that stains such as methylene blue, neutral red, and pyrrhol blue were attracted by certain tissues or tissue constituents, as, for example, fat and nerve tissues. These stains therefore could be considered to be specific in a sense, being now neurotropic, now neutrotropic, or lipotropic. The most perfect examples of such specific action are found in the behavior of the immune bodies that are attracted to the parasites, and not at all to the tissues of the organism, being purely parasitotropic in their action. The great difficulty with the therapeutic use of immune bodies has been the fact that they seemed not to be attracted by protozoa. Chemical remedies, on the other hand, have the disadvantage of possessing affinities, both for parasites and for tissues of the organism, and the whole task of experimental therapy in this connection is to find or make such chemical stuffs as would have the least possible injurious effect upon the body tissues while exercising powerful inhibitory effects upon the parasites. The substance least adapted for this purpose has proved to be corrosive sublimate,

which kills tissue cells in a concentration in which it does not seem to affect the bodies of parasites to any appreciable extent.

Some of the latest experiments of Ehrlich were devoted to the study of arsenic acid and its compounds. A number of compounds have been prepared which differ very much from the action of the original substance so far as poisonous qualities are concerned. The use of acetic acid as one of the components proved to be of most value, one combination, acetyl arsenilic acid, having shown to be almost nontoxic and at the same time capable of withstanding heating at high temperatures. Experiments with animals have shown that very dilute solutions of this substance were deadly to trypanosomes, while *in vitro* even very concentrated solutions proved to have no effect upon these organisms. The task was, of course, to explain this seeming contradition in the action of the new substance. Ehrlich prepared a number of compounds of arsenic acid and found that in test tubes the oxids possessed no inhibitory action as far as trypanosomes were concerned, while reduced substances were very active poisons to these protozoa. These experiments established the fact that the non-reduced substances were active poisons to the trypanosomes in the organisms of animals because the tissues of the animal were capable of reducing these substances; in the test-tube, on the other hand, the reduced substances alone were capable of such action. The analogy of the phenomena observed in the animal body and in the test-tubes was complete if the different facts in each case were allowed for.

Another fundamental difference depends upon the different valencies of arsenic; thus trypanosomes combine with the trivalent substance, but not with the pentavalent substance. By means of immunization strains of trypanosomes may be raised that are quite immune to poisons; if in any series of experiments the results seem to be unusual, not the animal may be at fault, but this newly-acquired property of the parasites. It has been found further that this immunity to poisons may reach a very high degree and may be transmitted from generation to generation of parasites. Moreover, not only the same preparation is impotent against such parasites, but all substances of the same class are equally unable to affect them. This fact allows us to measure the effectiveness of any preparation in comparison to others; if a preparation succeeds in destroying parasites that are immune to a certain class of remedies, then the new chemical is more powerful in this respect than the members of the former class of drugs.

In order to explain the series of phenomena that take place in the animal body in this connection, Ehrlich uses the conception of receptors that was originated by him. Arsenophenylglycin is a substance which has an absolute curative power, that is, it is effective even against trypanosomes that are immune to other arsenic compounds. We must consider it probable that a loss of receptors takes place in the first occasion, and this results in the diminution of sensitiveness toward some arsenic preparations. The receptors that still remain are sensitive toward antimony and toward arsenophenylglycin. The next stage is marked by the loss of receptors with which the sensitiveness toward antimony is likewise lost; the third step in the immunization would be the loss of all sensitiveness toward the arsenophenylglycin.

The aim of all such experimental work is to find substances that act in the body of the human being in a manner similar to the action of the arsenophenylglycin in the bodies of mice. Such a substance can be produced only with the help of chemistry, and one must hope that in the future too the relation between medical science and the chemical factories will be of the best, so that experimental therapy should find no hindrance to its work.

A few weeks ago there occurred the death of Friedrich Althoff. He was an official in the Ministry of Education of Prussia, and succeeded in making his power felt in all questions regarding the universities. He possessed a wonderful amount of energy, and his natural gifts helped him to maintain himself in the high station which he had reached. The result has been that the whole university system of Prussia has followed the ideas and ideals of Althoff; as the various faculties used to exercise a great deal of independence in all that concerns university life, conflicts between them and Althoff were quite frequent. As the scientist is usually a poor fighter by nature and by education, the victory in these conflicts usually remained on the side of the official. It is difficult to say how much of the recent changes in the universities was due to the activity of Althoff. It is a fact, however, that many of the modern clinics have been erected under his auspices and that the post-graduate courses were developed in his administration; the distribution of titles in Althoff's time has been different from older days, when the university titles were given out very rarely in comparison with the custom in the matter introduced by him.

Progress of Medical Science.

Boston Medical and Surgical Journal, December 17, 1908.

Medical Inspection of Schools from the Standpoint of the Medical Inspector.—This paper is by three inspectors of the Boston School System, J. T. Sullivan, T. J. Murphy, and M. J. Cronin. They conclude (1) that the whole system of medical inspection, including physicians and nurses, be placed under the control of the Board of Health; (2) that a chief medical inspector be appointed, with deputies, if necessary, to have full authority over all, his function being to direct and control the work of the district inspectors and to see that each performs the duties required; also, through a supervising nurse, to direct the work of the nurses; (3) that the medical inspectors' powers be definitely determined and specifically set forth and that a proper compensation be given; (4) that the nurses be subordinate to the district medical inspectors and work only under their direction; (5) that a card system of records be devised, to be filled out by both physicians and nurses, one set to be kept at the schools and another set at the office of the chief medical inspector; (6) that the Board of Health and the School Committee cooperate in bringing about such needed reforms.

Chronic Intestinal Catarrh.—In this paper, continued from the previous issue of the Journal, L. C. Miller takes up the question of treatment, the former paper having described the condition, and takes up the matter of diagnosis, complications, and secondary conditions. Under treatment, the question of diet is carefully considered. For catarrh of the small bowel, the diet should be rich in albumen, meats, fish, eggs, as little sugar as possible, stale white bread or swieback, rice, sago, macaroni cooked in water, hot milk, bouillon or barley soup, butter, unsalted, weak tea and red wine. In some cases gas formation is so disagreeable that all carbohydrates must be cut off, vegetables containing cellulose should be avoided and fat taken only in limited amounts. As a rule milk is not well borne, but it may be the best food in certain diffuse catarrhs when the stomach and large bowel are most prominently affected. From one to two quarts of fluid are needed in the course of the 24 hours. In colitis, we may use coffee with milk, white wine, lemonade, apolinaris, and seltzer. Irrigations are commended, and their method of administration described. As to drugs, the author commends the use of tannigen, the bismuth preparations, the various intestinal antiseptics, mineral waters, etc. Bismuth subgallate is especially commended. With all remedies the preferable method of administration is to begin with as large a dose as the case will stand and diminish it gradually as improvement appears.

New York Medical Journal, December 19, 1908.

Treatment of Biliary Disease as Determined at the Operation.—Four case histories are given by H. Lilienthal. Case 1 was one of cholecystitis, in which gallstones were looked for but the operation revealed none, although the lumen of the cystic duct was so fine as to admit only the finest probe. The bladder was removed. Recovery was prompt and seems to be permanent. In Case 2, one of jaundice and glycosuria, the gall-bladder was found contracted and completely buried in hepatic tissue, and was literally dug out of its hepatic bed. In Case 3, a diagnosis of pericholecystitis with cholelithiasis was made. An abscess was found around the gall-bladder, and a single large calculus in the viscus itself. Later a large mass was washed from the wound, showing a hydatid cyst as a complicating lesion. Eventual recovery ensued. The author thinks it would have been dangerous to remove the gall-bladder at this primary operation, owing to the likelihood of serious infection. In Case 4 there was jaundice and great increase of liver dulness. The patient's bad general condition forbade more than a quick cholecystotomy under local anesthesia. The bladder full of pus and stones was drained with eventual cessation of the jaundice. The liver shrank, but at a secondary operation the gall-bladder was removed, a stone taken from the common duct and recovery ensued. The author says that one should never close the abdomen, except in the presence of collapse, without examining the pylorus and the pancreas. If white or yellow plaques of fat necrosis are seen in the omentum or mesentery, it means that the bile passages should be

drained, preferably by cholecystostomy, whether stones are present or not. The fat necrosis indicates the presence of acute pancreatitis, a diagnosis which is very rarely made before operation. In concluding his paper, the author emphasizes the following technical points: First, use but little gauze packing, even of the temporary variety. Many operators are absurdly afraid of soiling the peritoneum with a few drops of bile or pus. Infection, perhaps dangerous, may follow the soiling of the handled and damaged peritoneum, but the mere presence of bile or even pus will not cause general septic peritonitis unless the integrity of the peritoneum has been impaired by rough handling or contact with gauze. Another reason for avoiding packings is that they tend to produce adhesions, which may not only be embarrassing should a secondary operation be necessary, but which may in themselves give rise to complete or incomplete obstruction, particularly in the neighborhood of the pylorus. Second, in case of common duct disease this structure is more easily reached and manipulated when the gall-bladder has been removed and the cystic duct drawn up by traction sutures. The stump of the gall-bladder having been secured, it is not usually difficult to slit the duct with scissors down into the common duct. Hemorrhage may be accurately checked and the work can go on in a quiet and orderly manner under the eye. Third, leave the traction sutures in place. It may be that in spite of every precaution recurrent bleeding occurs. If the traction sutures are in place it is but the work of a few seconds to reopen the wound and draw into view the parts where the trouble is most frequently found.

Hemorrhage into the Vitreous Body in the Adolescent.—J. A. Gehrung records the histories of two cases and presents the following conclusions: (1) Hemorrhage into the vitreous body during adolescence is quite frequent, and owing to the danger of recurrence, and tissue changes in the eye, is a dangerous condition, worthy not only of patient, careful, and exhaustive treatment after the occurrence, but also of prophylactic measures; (2) the too rapid development of children should cause solicitude; (3) rapid changes of temperature and prolonged exposures to heat or cold are etiological factors; (4) menstrual disturbances, undue sexual excitement and abuse, cardiac disease, dyscrasias, malnutrition, errors of refraction, all causes of eye strain, hereditary diseases and tendencies, vascular diseases, anemias, abnormal (premature?) development, or malformations, all mental and physical causes of sudden and rapid fluctuations of the blood stream and tension are causative factors in intraocular hemorrhages; (5) the origin of hemorrhages may be from the retinal vessels or from the vessels in the region of the ciliary body, not from the sheath, etc., of the optic nerve; (6) glaucoma is rather the result than a causative factor of these hemorrhages; (7) the treatment should be medicinal if possible, the knife to be used only as a dernier resort; (8) attacks in women usually follow menstrual disturbances; (9) where there is a tendency to epistaxis and this suddenly ceases we have a danger signal of hemorrhage; (10) males are more liable to intraocular hemorrhage than women; normal menstruation is seemingly a safeguard; (11) the age from puberty through womanhood, or manhood, is a danger period; (12) anemic conditions are predisposing.

Is Not the Tubercle Bacillus the Cause of Cancer?—T. G. McConkey believes that the B. tuberculosis is the fundamental cause of malignant growths. He reviews the statements of various authorities on the relation of the tubercle to the bacillus, stating that it serves the latter's interest by protecting it from phagocytosis and thus permitting it to exist for years in a latent state. He claims that the bacilli can originate lesions which give no microscopic evidence of their causation; that even in the most typical tuberculous lesions it is frequently impossible to demonstrate a single bacillus by the ordinary methods; that not only are inoculation experiments not contradictory, but are even best explained by this theory; that the tuberculous and cancerous processes are frequently found not only in the same patient, but in the same growth; that caseation which is so characteristic of tuberculosis is also found in cancer; that conditions formerly called cancer are now known to be tuberculous. He claims that the fact that tubercle bacilli set up cell proliferation when they find lodgment in connective tissue, and epithelial or endothelial cells, and that this fact is of compelling significance in furnishing the solution of the cancer problem. He claims that this theory of the etiology of cancer is equally satisfactory when examined from the clinical side. Various quotations are made from the writings of various authorities on malignant growths. Special attention is called to the analogies between tubercle and cancer. Thus, both are hereditary in the sense of showing a family predisposition; both show an age incidence; both purely local at first; both may become general; both may result from trauma; both found not only in man, but in other vertebrates; both have location incidence in certain tissues; both show difference in appearance and structure, depending on tissue affected; both may have as predisposing cause depressing influences, as worry, grief, etc.; both have wasting and cachexia; both have race incidence; both have house and district incidence. These striking analogies are plain if we consider the conditions as different manifestations of one infectious agent, and the apparent antagonisms are also thus satisfactorily accounted for.

Journal of the American Medical Association, December 19, 1908.

Cerebral Hemorrhage.—W. G. Spiller does not find, in his experience, the diagnosis of cerebral hemorrhage justified in cases of death occurring within five or ten minutes after the beginning of the attack. He gives the details of thirteen cases, with autopsies, in which life was prolonged for hours after the onset of the apoplectic attack, even when the hemorrhage was extensive, had broken into the ventricles and filled them all, even the fourth. As a rule extensive hemorrhage into the lateral ventricles is followed by a more rapid death than when the ventricles escape, but a moderate hemorrhagic exudate into the ventricles is not necessarily rapidly fatal. Even a large part of one cerebral hemisphere may be destroyed and the patient live for a considerable period, as was shown in one of his cases in which the hemorrhage destroyed the lenticular nucleus, a large part of the posterior limb of the internal capsule, and extended to the island of Reil, and yet the patient lived nearly two months.

The Sphenoidal Sinus.—J. A. Gibson describes the anatomy and variations of the sphenoidal sinus, a cavity of which he thinks the importance has been underestimated and its study neglected. He has investigated 85 sphenoidal sinuses in the human skull, with especial reference to the position, size, and extent of the sinus, the average thickness of its walls, its relationship in size, if any, between it and the frontal and maxillary sinuses, the relationship, if any, between a large posterior naris and a small sphenoidal sinus, or the reverse, the establishment of certain averages between anatomic points, obtainable in the living subject, which might be of assistance to the surgeon, and to the recording of anomalies and their possible influence on surrounding parts. He finds no definite relationship in size between the different bony sinuses of the skull, nor anything definitely characteristic between the sizes of the posterior nares and the sphenoidal sinus. The size of the posterior nares is a very poor guide in estimating the size of the sinus. Any operation approaching the sinus by way of the postnasal space and from below would be unsatisfactory in many cases from the fact that the floor is sometimes quite thick, and that the sinus is often situated far forward. Any rule for the passage of a catheter into the sphenoidal sinus must necessarily be imperfect if for no other reason than that the nasal turbinates vary greatly. Added to this is the liability of variation of the sinus opening. Adding the minimum distance from the anterior superior nasal spine to shortest anteroposterior sinus, Gibson gets as a result 57 mm. (2¼ inches). This will give the least distance from the anterior nasal spine to the posterior wall of the sinus, and furnish a conservative distance to which an instrument may be inserted without fear of entering the cranial cavity.

Alveolitis.—M. H. Fletcher considers alveolitis, commonly called pyorrhea alveolaris, one of the most prevalent and destructive disorders attacking the teeth. Its initial exciting cause is, in his opinion, the formation of tartar about the necks of the teeth. This sets up irritation and invites infection which destroys the membranes covering the alveoli and dental roots. The infection is most likely to be from the pus-producing germs attacking bone, those of syphilis and tuberculosis. Fletcher thinks the last-named infection the most frequent, though its microscopic determination is not easy. Syphilitic infection seems to be much less common in these cases than either the pyogenic or tuberculous, though the mouth is a favorable location of other syphilitic lesions. The necrotic process may extend, invading the maxilla and antrum in extreme cases, and sometimes giving rise to severe neuralgic symptoms in regions apparently free from the disease. This Fletcher is inclined to attribute to a periostitis

starting from the alveolitis. He goes fully into the treatment, the removal of calcareous deposits and necrosed bone, the description of instruments, etc., and claims that by proper handling even the advanced cases can often be conservatively treated without the radical operation of extensive removal of maxillary structures, as is now so often done by the general surgeon. The necessity of thorough curetting or burring about all teeth where the disease is found and of more thorough removal, if the disease is deep-seated, is particularly insisted on. Of course, the general condition and resistance are factors to be considered, and if systemic treatment is required it should be directed toward the restoration of normal health by such means as the elimination from the diet of foods, which do not become fully digested or assimilated, and the copious drinking of pure water. Any complicating disorders, aside from the local disease, should be properly attended to.

Amebic Dysentery.—J. M. Holt argues the necessity of surgical treatment for all cases of chronic amebic dysentery in which, after a fair trial of other treatment, the *Ameba coli* can still be found in the stools. All observers, he says, are agreed as to the tendency of the disease to resist treatment and to run on indefinitely, and we should not permit this when a simple surgical operation will clear up matters at once. There are altogether too many patients in the country going about uncured for years, and he asks: Has appendicostomy ever been proposed to them? While there may be a debatable ground for the adherents of the medical treatment of appendicitis, there is none in this case. A case, he holds, may be considered no longer acute and amenable to radical treatment after it has lasted nine months or a year. In his opinion, however, there is no known drug which given by the mouth, can be tolerated in the upper digestive tract in sufficient strength to destroy the ameba in the colon. In conclusion, he suggests the possibility that the *Ameba coli* may not be equally pathogenic to all, as some do not contract the disease after exposure. The so-called *Entameba coli* may be the form of parasite found in the stools of individuals not thus susceptible. The so-called *Entameba dysenteriæ* may be the same parasite developing greater activity, coincident with morphologic changes in an individual having a susceptibility to the organism. He asks whether it has ever been found in a case presenting no clinical symptoms.

Syphilis Diagnosis.—Wassermann's statement that his syphilitic serum reaction is reliable only with the use of extracts made with physiological salt solution has been experimentally tested as to its correctness by J. W. Marchildon. His experiments were carried out in Professor His's laboratory in Berlin, and the results are given by him as follows: 1. Alcoholic extracts may be safely used in the reaction for the serum diagnosis of syphilis, because they in no way differ from watery extracts. 2. There are some non-syphilitic blood sera which give a positive Wassermann reaction. These sera, however, are so rarely met, and then only in such extensive pathological processes, that they do not vitiate the clinical value of the reaction.

Hydrophobia.—F. W. Dudley has personal knowledge of thirteen persons in the Philippine Islands dying of this disease and has records of ninety-one deaths from board of health reports and of fifty-four deaths from correspondence with physicians, making a total of 106 deaths within a period of three or four years. It is unusual for persons bitten to seek medical treatment. Since he sent out his inquiries he has also received telegrams asking for antirabic virus from physicians who had in their charge cases of the disease. It is as frequent in the winter months as in the summer, and most of the cases occur in males, owing to their greater exposure. Dudley reviews the etiology, pathology, and morbid anatomy and bacteriology so far as known according to the best authorities. The average period of incubation in the Philippines seems to be rather long. The three longest authentic cases reported were eight, nine, and ten months. Cases of pseudohydrophobia have also occurred, but were not fatal. Many curious remedies are used in the Philippines, one of which is to burn the hair and brain of the animal and apply the ashes to the wound, but there has been no record of recovery of an authentic developed case there or elsewhere.

Cholesterin in Pernicious Anemia.—C. E. Simon reports his experience with cholesterin in six cases of the disease. His trial of the substance was made, for the same reasons as that of Reicher, over a year ago, but the material being so limited he delayed publication until incited thereto by the appearance of Reicher's article. All six of his cases were typical cryptogenetic pernicious anemia, one being of the so-called aplastic type. In three advanced cases no effect was observed. A fourth patient was discharged unimproved after a three weeks' trial, and in a fifth death occurred before more than twenty-four grams had been administered. In the sixth patient an apparently beneficial effect was produced, but, as it was the first attack, one naturally hesitates in ascribing it to the drug. It is noteworthy, however, that the same effect followed its use in a relapse which occurred some months later. The patient is still living and in good condition. "When first seen the red cells numbered 1,744,000, while the hemoglobin was 46 per cent.; there was then marked anisocytosis with a distinct tendency to macrocytosis; there was poikilocytosis and extensive granular degeneration (so-called). Normoblasts with pyknotic and caryolitic nuclei were fairly numerous; there were some free nuclei and a few mitotic cells; megaloblasts were scant. After a three weeks' course of cholesterin, the red cells had increased to 4,000,000 and the hemoglobin to 80 per cent. Anisocytosis was still noticeable, but less marked than before; granular degeneration was slight and there were no nucleated red cells. Subsequently the anemia became more marked again, but, as I said before, the patient again improved and at the present time is well." Cholesterin is apparently nontoxic, but it is costly. So far as Simon's results show, it would seem to have little value in advanced cases, but may have some utility in early cases.

The Lancet, December 12, 1908.

Rupture of the Ligamentum Patellæ.—One case is reported by Dr. Paravicini, who describes his own personal experience. While running down a slope covered with snow, he slipped and fell, the left heel touching the left buttock and the leg being completely doubled. He felt a crack and an acute pain and was unable to stretch the leg by its own force. Through the clothing a gap was noticed below the patella, which was drawn up by the quadriceps extensor. After crawling for some two hours, he was picked up and taken to a hospital, where a radiogram revealed a rupture of the patellar ligament. A colleague opened the knee-joint by a vertical incision over the patella and the ligament, removed the accumulated blood clots, and fixed the ligament, which was completely torn through, to the lower border of the patella by strong silk sutures. The leg was immobilized. There were some fever, pain, and an increasing swelling of the joint, symptoms which a puncture proved to be due to a turbid serous exudation, necessitating a second intervention of the surgeon a week after the first operation. After reopening the wound and removing a few stitches, incisions were made on both sides of the joint and the articulation was kept drained for a fortnight. The first incision healed by granulation, leaving a big scar adhering to the patella and the ligament. After several months of massage and exercise the author was able to engage in most sports except climbing. Going down steep slopes is still, six years after the accident, very difficult for him. The leg can be bent to an angle of about 30 degrees.

The Agglutinating Power in Tuberculous Patients; Serum Diagnosis and Serum Prognosis.—Paul Courmont discusses the history and enumerates the proofs of the value of serum diagnosis in tuberculosis. The advantages of serum diagnosis as compared with tuberculin reactions are: (1) Absolute harmlessness, since the taking of a little blood cannot give rise to accidents or inconvenience, which cannot always be said of the tuberculin and ophthalmoreactions. (2) Facility of application, since a few drops of blood suffice and it is not necessary to watch the patients during the course of several days, as in the other two methods. (3) Importance of the variations of the agglutinating power. Given the harmlessness and facility of application one can repeat the reaction as often as one likes, and the variations of the agglutinating power are of great importance not only for the diagnosis but also for the prognosis. (4) Applications of local serum diagnosis. As to prognostic value the author advances the following arguments: (1) General statistics.—In tuberculous subjects in whom the serum is not agglutinative from 10 to 15 per cent. are nearly all very seriously ill. The subjects who have advanced consumption, miliary tuberculosis, caseous pneumonia, and meningitis have nearly all a negative serum reaction. (2) Experiments in animals rendered artificially tuberculous.—The development of the agglutin-

nating power is the more marked when the tuberculosis is less virulent and the animal more resistant and conversely. (3) Variations of intensity in the agglutinating power of the tuberculous.—These variations appear to be dependent on the gravity and progress of the disease. Very marked reactions are found especially in subjects in whom the tuberculosis is slight or becoming quiescent (local tuberculosis of the viscera, fibroid tuberculosis of the lungs, primitive pleural tuberculosis of Landouzy, etc.)—Reciprocally slight agglutinations are found especially in patients more seriously ill. (4) Variations of the agglutinating power in the same subject.—If one watches for a long period of time a particular tuberculous subject one frequently sees the agglutinating power of his serum rise if the patient improves, and on the contrary fall if the illness becomes worse, and at times even disappears comnletely. Here are some examples of these two variations: (5) Mortality of tuberculous pleurisy. Considered in relation to the agglutinating power of the pleuritic fluid of 120 cases kept under observation 75 per cent. of cases were cured, having a positive reaction, while 73 per cent. died, having a negative reaction. We cannot reproduce the author's conclusions *in extenso*, but refer to one or two points. First, limitations of the method. Given that the agglutinating power of normal serum varies according to age and also to the animal species investigated, serum reaction has a diagnostic value only when the degree of agglutination is higher than the ordinary degree of agglutinating power of the serum of normal individuals of the same age and belonging to the same species. Second, serum diagnosis. For practical purposes serum reaction must be applied with great clinical discrimination; its results must be compared with the other symptoms and not interpreted blindly. It would not be wise to regard a patient as clinically tuberculous for the sole reason that his serum agglutinates Koch's bacilli. The reaction can have no diagnostic value unless there are other reasons justifying the suspicion of tuberculosis. In such cases, however, a positive serum reaction has a great value; negative reaction is of less value. Third, nature and prognostic value of serum reaction in tuberculous patients, serum diagnosis. As is the case in many other diseases the agglutinating power of blood serum and other organic liquids in tuberculosis is proportional to the resisting power of the patients; furthermore, it is in an inverse ratio with the virulence of infection. Serum reaction is frequently absent in very serious or very advanced cases of tuberculosis. It reaches its maximum height in cases which are in the process of healing. It can diminish or disappear sometimes before death; it can, on the contrary, increase when there is a tendency towards healing or towards arrest. It seems to be an index of the protective reaction of the system. Fourth, in tuberculous pleurisy with effusion and increasing agglutinating power carries with it a good prognosis but failing any reaction, one must be prepared sooner or later for a fatal result.

A Case of Neurasthenia Complicated with Vasovagal Attacks.—The patient of M. M. Burgess was a woman of 39 years with typhoid neurasthenic symptoms and subject to attacks of extreme fatigue amounting almost to loss of power. The patient usually turned to one side and lay quite motionless and relaxed, the extremities were cold and there was increasing pallor until the face became ashy gray. The skin was dry; there was no cold, clammy perspiration, as in an ordinary fainting attack. The pupils dilated in the worst attack and in all the eyelids were kept separated; the eyes rolled slightly and blinking was almost arrested for the time. The pulse became exceedingly infrequent, of low tension, and at times almose imperceptible to the touch; the breathing was shallow, hurried, and costal in type. The patient did not willingly speak, but answered in monosyllables if spoken to. She was so "bowled over" that she had no energy even to call attention to her condition. Until the nurse was told to be on the watch for the attacks she would have one and recover without its being noticed, and she would merely remark afterwards that she had felt "dished" again. The attacks ended with a deep-drawn breath or sigh, and if any one was sitting by her she would remark, "That's all over now; I am better again." The attacks were very alarming. They in no way resembled an ordinary fainting attack. Their duration was about ten minutes. There was an entire absence of pain, tetanoid spasm, rigor, tingling or anything suggestive of epilepsy. Consciousness was unimpaired, but there was a sense of impending death. Whether in this case there was some affection of the vasomotor center alone which secondarily caused the bradycardia or whether the cardioinhibitory center was also affected is uncertain. The evidence seems to point to a primary affection of the brain centers as there was nothing to show the attacks could have had a reflex origin from nerve irritation. If the attacks were not of vasomotor origin at all another possible explanation seems to be that, after any special exertion the heart, as it were, went on strike and a functional disturbance resulted, showing itself in slow and insufficient muscular action. But were the cause of the attacks primary muscular insufficiency with normal blood pressure dilation would probably have occurred. This evidently did not happen, as neither the symptoms nor the physical signs showed that condition.

British Medical Journal, December 12, 1908.

A Method of Enucleating the Appendix.—L. H. Harris claims for the following method the merit of simplicity: Make a circular incision through the serous coat near the base and then introduce an ordinary blunt pointed hook, the lower end of which has been bent at a right angle, and encircle the stump in a manner similar to that in which an aneurysm needle embraces a vessel, make a gentle movement downward in the direction of the appendix, and usually in a few seconds the enucleation is complete. The stump is then treated in the usual manner, and, as there are no vessels to tie, the whole operation is completed in a comparatively short period.

A Case of Buphthalmia.—A case of this rare condition is reported by J. H. McIlroy in the person of a boy of 5 years. When first seen the following condition was noted: Naming watch, teaspoon, penny at 1 ft. Size of pupil, about 6 or 7 mm. Reactions of pupils and ophthalmoscopic examination not obtained on account of photophobia. L. V. = probably no perception of light. Opacity in pupil, probably lens. R. and L. constant fine lateral nystagmus. T. = + 1 (at least). A. C.'s very deep. Corneæ very nebulous all over. Corneæ extremely large, difficult to measure owing to patient's resisting opening of the lids. Avoids the light by keeping head depressed. Is able, however, to keep eyes wide open. Marked iridodonesis. Eyeballs covered by lids during sleep. Eight years later the condition was practically the same. The treatment consisted in installation of drops of a one-half per cent. solution of eserine to the right eye every six hours. The boy's general condition is normal. The author regards the case as evidently one of congenital buphthalmia, or infantile glaucoma. The etiology of these cases is obscure, the condition probably being established *in utero*. There is nothing in the history of this case to account for the condition. Consanguinity of parents, which seems to be a frequent factor, is absent here. The patient is one of a large family, none of whom seem to suffer from any allied developmental defect, for example, aniridia, etc. The mother had one miscarriage (previous to birth of patient) which seems to have resulted from accident rather than disease. One child died in infancy of convulsions, but all the other members of the family have grown up healthy. The author notes the extremely slow progress of the disease, the condition not having changed to any great extent during the last eight years. In this it differs considerably from the analogous condition of glaucoma in the adult, where degenerative changes take place more quickly. In the infant the tissues of the eyeball are plastic, and distension of the coats of the eye takes place without destruction of the underlying tissues (retina, choroid, etc.). The involvement of the latter, as a rule, takes place only at a much later stage. In the present case, although there is great thinning of the cornea and sclerotic, the fair amount of vision indicates that the visual structures proper are tolerably intact. The dimness of vision would be accounted for by the blurred cornea and cataractous lenses.

Spontaneous Rupture of the Gall-Bladder.—P. F. Braithwaite reports the case of the sudden death of a man of 45 years. Five months previously he had dull abdominal pains in the right iliac region which were regarded as due to a mild appendicitis and which were cleared up in a week. On autopsy a small gallstone was found free in the abdominal cavity and a small perforation was found on the posterior surface of the fundus of the gall-bladder. One stone was found impacted at the junction of the bladder and cystic duct. Around the perforation the bladder was so thinned as to show clearly the muscular stone in its walls, while the rest of the bladder wall was abnormally thick and tough. What had evidently taken place was that the constant irritation of the gallstones had caused marked thickening of the walls all over the gall-bladder, excepting at the place where a constant pressure, probably increased by the blocking of the cystic duct, had caused marked thinning, resulting in the sudden perforation, which did not occur during any special muscular exertion. This sudden perforation apparently caused fatal syncope so abruptly that the man had not time to utter a single word. The attack of pain he had five months previously was possibly

the occasion when the stone, found at the entrance to the cystic duct, became impacted there, or it was possibly due to the passage of a small gallstone, though the character of the pain did not suggest that.

An Epidemic of Influenza Characterized by Edema of the Eyelids.—N. I. Spriggs believes that edema of the eyelids with severe frontal headache, which may or may not be followed by pyrexia and other general symptoms, may be an early expression of an influenza. Some ten cases occurring in the practice of several physicians are recorded by him. The occurrence of these symptoms in influenza is noted by Finkler in the article on "Influenza in the Twentieth Century Dictionary of Medicine." Of the group of cases here reported about half had other influenzal symptoms. Apart from the latter, a differential diagnosis would call for the consideration of a frontal sinusitis and angioneurotic edema. Cultures from the conjunctival sacs in the foregoing cases have shown variously *Bacillus xerosis*, and *Staphylococcus albus*. Some of the cases were entirely afebrile and soon subsided. No albuminuria was found. For local treatment the author found boric acid washes and cold compresses satisfactory.

Münchener medizinische Wochenschrift, November 24 and December 1, 1908.

Asepsis in Obstetrics.—Krönig of Freiburg objects to the complicated aseptic technique in obstetrics and to the modern "era of rubber"; according to him the introduction of rubber gloves has not led to any diminution in mortality or morbidity in normal labors. He thinks that the prescribed disinfection of the hands and of the woman in labor are too lengthy and too bothersome. His principles are: to have if possible no disinfection whatever of the external or the internal genitals; to conduct the labor in such a manner that the doctor likewise need not disinfect his hands; to lay all stress upon the local and general predispositions to infection and to do away with these as far as possible. The principle of freedom from germs is an impossible and an incorrect one, the disinfection of vagina having shown, for instance, that worse results attend such an attempt; the effective disinfection of the vulva is also impossible, unless shaving of the pubic hair is insisted upon in every case. The latter is possible and ought to be done in case of any operative procedures, when effective disinfection is attained during anesthesia. To escape the dangers of internal examinations Krönig teaches palpation per rectum and thinks that the results compare favorably with any other method. Protection of the perineum is limited in his clinic to primipara and thick rubber gloves are used for this purpose. There is no disinfection after labor is over. The puerpera is allowed to leave the bed on the first day, if possible, this procedure diminishing the local predisposition to infection of the uterus. Krönig finally compares the results of above methods with the figures of Hofmeier's clinic in which elaborate aseptic precautions are exercised; he claims that his results are in no way worse than those of Hofmeier in regard either to mortality or the morbidity. Indeed, since the aseptic measures have been curtailed more favorable results have followed.

Parabiosis.—Morpurgo has succeeded in sewing together and keeping alive white rats of opposite sexes and finds that the operation is not followed by any changes in the genital organs of the animals. Death has followed in a few weeks as a result of the operation, the stronger animal apparently living at the expense of the weaker one; one pair, however, has lived for three months. No coordination of movements or any agreement develops in such animals; the individuals act as two independent beings and interfere with each other very much.

Dysmenorrhea.—Veit says that the condition of the endometrium is dependent upon ovulation and many appearances that previously were looked upon as pathological are simply the physiological conditions present in the menstrual or post-menstrual time. This recent view diminishes the number of anatomical lesions which can be held responsible for the symptom dysmenorrhea. Veit defines menstruation as the abortion of an unfertilized ovum; ovulation should naturally be followed by impregnation, but as it does not every time in the human race the various phenomena of ovulation must be conquered, which adaptation is outwardly shown by the function of menstruation. A nervous individual may react abnormally to the impulses of ovulation; in her the phenomena of conquering such impulses may not occur and the result is one of the forms of nervous dysmenorrhea. Another form is due to the faulty development of the uterus with coexistent abundant sexual excitement; the latter leads to changes in the ovaries and in the endometrium and to the symptom of dysmenorrhea, which in this case depends upon both anatomical and functional disturbances. The third form is the purely mechanical one due to some local disease or anomaly of the uterus or of the neighboring organs. The nervous forms of dysmenorrhea are to be treated by measures affecting the general health or by directing the treatment upon some possible source of peripheral irritation, attention to which may have a salutary psychic effect. The latter mode of treatment may include the cocainization of the nasal mucosa, a procedure by which Fliess claimed to cure all cases of dysmenorrhea whatever. In all dysmenorrheas of virgins the patient must be examined for neurasthenia and the latter disease treated, if present, rather than the symptom of it in the genital sphere. In case neurasthenic symptoms are absent a gynecological examination and eventually operative treatment in the form of a curettage may be tried.

Wassermann's Reaction.—Bering says that Wassermann's reaction simplified according to the method of Bauer is just as trustworthy as in its original form. The reaction in question is of great practical importance, the fact that over three hundred cases were sent to him for differential diagnosis by means of the reaction showing the uncertainty that is frequently present in diagnosing syphilitic infection. Patients in the primary stage of the disease but rarely give a positive reaction; of those in the secondary stage, on the other hand, only 2 per cent. failed to give positive evidence of a syphilitic reaction. The value of this new diagnostic method can hardly be overestimated. It enables a positive diagnosis in cases where the infection with syphilis is denied or is forgotten; it furthers prophylaxis by discovering infection in wet-nurses, nurse maids and all other persons that come into close contact with children; it gives a positive answer to the neurasthenics suffering from syphilophobia and going from one physician to another in the fear of having been infected with the disease; it enables the physician to decide which of the parents is to be treated more thoroughly in cases of abortion and stillbirths; finally, it is of utmost use in the differentiation of tertiary lesions of gummatous nature from inflammatory or malignant tumors. To a certain extent, too, it gives a clue to the effect of treatment, for the use of mercury and of iodides often leads to the disappearance of the positive reaction, which may again reappear if treatment is not conscientiously carried out. In the same number of this journal, Fraenkel and Much give their experience with the Wassermann reaction at autopsies. They had very good success with it and see in it a valuable aid to the pathologist in diagnosing questionable lesions found at autopsies. Control experiments showed the specificity of the reaction, with one exception: the blood of scarlet fever patients gave a reaction very similar to that obtained with the blood of luetics.

Retroperitoneal Ganglioneuroma.—Oelsner reviews the few reported cases of this tumor and reports a case of his own. His patient was a woman, 20 years old, who suffered from severe pains in the left lower abdominal quadrant. Examination showed a mass in the left epigastrium that was movable in the lateral direction, but did not move with respiration and could not be displaced in the direction of the vertical axis of the body. The kidneys were normal functionally and to palpation, the gastro-intestinal tract likewise normal. Diagnosis of a retroperitoneal tumor was made. Kocher operated and removed a large tumor, encapsulated, which on cross section appeared poor in blood-vessels, but seemed very succulent because of abundant lymph content. Microscopically the tumor proved to be a ganglioneuroma. During the post-operative course the patient was attacked with acute appendicitis and was again operated upon. Oelsner remarks upon the frequency of collapse phenomena after the removal of such tumors and thinks that the cause of them may possibly be found in the shock to the sympathetic nervous system caused by the operation; the attack of appendicitis may likewise have been due to the diminished resistance of the tissues because of a temporary interference with the functions of the sympathetic.

Rôle of the Pituitary Membrane in the Pathogeny of Lupus Vulgaris of the Face.—Henri Caboche asserts that there is an important relation between lupus vulgaris of the face and lupus of the pituitary membrane. It is in the immense majority of cases propagated from the mucous membrane by way of the lymphatics. The simple treatment of the nasal mucous membrane in some cases causes retrogression of the face lesions, and inversely, a subsisting nasal lesion is a cause of perpetual reinoculation of the integument.—*Lo Presse Médicale.*

Book Reviews.

Clinical Diagnosis. A Text-book of Clinical Microscopy and Clinical Chemistry for Medical Students, Laboratory Workers, and Practitioners of Medicine. By Charles Phillips Emerson, A.B., M.D., Late Resident Physician, the Johns Hopkins Hospital; and Associate in Medicine, the Johns Hopkins University. Second Edition. Philadelphia and London: J. B. Lippincott Company, 1908.

The second edition of Emerson's "Clinical Diagnosis" has involved the rewriting of fully one-half the work, and has given opportunity for the introduction of a considerable amount of new material. The object of the revision, according to the preface, has been to raise the efficiency of the book as a working manual. In looking over the work in its present form we cannot but express our commendation as to the manner in which the subject is presented. The clinical side of all laboratory methods is constantly kept to the fore, and although many of the methods given are far too elaborate for the practitioner, or even for the clinical laboratory doing the routine work of a hospital, the work is of great value as a reference book for physicians in aiding them to apply scientific methods in cases in which time and trouble are not of importance. The simpler clinical methods are not neglected, however, so that the practitioner will find in the book plenty of ways of doing his laboratory work himself. The book is nevertheless essentially for medical students and for laboratory workers. These will find in it all that they require for good and efficient work, and for a thorough understanding of the clinical significance of their findings.

Elementi di Röntgenologia Clinica. (Tecnica, Diagnostica, Terapia). Dott I. Valobra, Medico dell 'Ospedale Mauriziano Umberto I di Torino. Con 95 Figure intercalate nel testo e sei Tavole. Prefazione del Prof. Camillo Bozzolo, Direttore della Clinica Medica Generale della R. Università di Torino. Turin: S. Lattes & Co., 1908.

This manual of Röntgenology opens with a brief consideration of the physics of the *x*-rays, and a concise description of the apparatus and technique employed in this work. The second part of the book is devoted to the diagnostic value of the rays; the third to their therapeutic application. The work is written in a very clear, easily-grasped manner, and all technical subjects are dealt with in such a way that the practitioner who has forgotten his electrophysics can readily follow the text. Much attention is given to perfection in technique, including the various modes of measuring the quality and quantity of the *x*-rays used, the appliances for orthoröntgenography, etc. Complete and precise directions are given for the development of plates, for printing radiographs, for stereoscopy, etc. In the clinical sections each region of the body is considered in detail and its possibilities from the viewpoint of *x*-ray diagnosis are discussed. The illustrations are for the most part very clear and sharp. Much attention is given to the interpretation of plates—one of the most difficult tasks of the röntgenologists. Dr. Valobra's book represents a very complete and very satisfactory monograph on the modern status of the *x*-ray in medicine, and is based on a great deal of careful *x*-ray work on the part of the author.

Erdsalzarmut und Entartung. Von Hofrat Dr. Med. C. Röse. Berlin: Julius Springer, 1908.

This monograph of 156 octavo pages is devoted to the presentation of arguments, statistics and experiments for the purpose of demonstrating that the apparent decadence of the human race, coincident with modern civilization, is due to a lack of earthy mineral matter consumed—principally to a lack of calcium salts. The author is a dentist who has devoted a number of years to the study of this question, and who complains about the indifference with which his earlier publications on this theme have been received by the medical profession. In his experience persons who live in localities supplied by "hard" drinking water are healthier, have better teeth, etc., than people living in places supplied with "soft" or calcium-poor water. The latter class live in the great cities and industrial centers where those enemies of humanity, locomotives, engine boilers, etc., must be supplied at all costs of human life with calcium-free water. Military enthusiasts will find in Dr. Röse's book interesting data showing that lack of calcium salts is a cause of a greater number of rejected recruits from the localities afflicted with calcium-poor water. The physical effects of overcrowding, lack of air, of proper fresh food, of poverty, of overwork and of such diseases as tuberculosis, for example—factors which predominate in great cities, alongside with calcium-poor water, are not of importance in the eyes of the author. The book contains a great deal of valuable material, but the subject is handled in a too one-sided manner to permit the work to be ranked as a scientific contribution of great importance.

Malformazioni dell' Utero nei loro Rapporti colle Funzioni di Maternità. Tesi di libera docenza. Dott Andrea Boni, Aiuto alla Clinica Ostetrico-Ginecologica della R. Università di Pisa. Pisa: Typografia A. Valenti, 1907.

The importance of malformations of the uterus in pregnancy and labor has been recognized but recently. In 1901 Dr. Boni published a collection of 207 cases of uterus bicornis as affecting the course of pregnancy, labor and the puerperium, adding 3 cases observed at Pisa. In the present thesis he takes up systematically all the deformities and malformations of the uterus and considers them from the same viewpoint in the light of the cases published in the literature, as well as of the cases personally observed. The work, therefore, is arranged on the same plan as Kussmaul's famous monograph which appeared in Würzburg in 1859. The literature of the entire subject has been brought up to date and the cases have been tabulated at the end of the volume. This monograph should prove of great interest to those who wish to study the relation of uterine anomalies to the functions of motherhood, and shows a great amount of study and research in this particular field.

Cholécysto-Pancréatite. Essai de Pathogénie. Par le Docteur Reine Maugeret, Ancien Interne des Hôpitaux de Paris. Paris: Steinheil, 1908.

Dr. Maugeret presents in this essay a study of the pathogenesis of pancreatitis due to gall-bladder lesions. The views upon which the work was based were those of Prof. Thiroloix. When pancreatitis is present with cholelithiasis, the former is not an independent condition, but is a complication of the latter. This type of pancreatitis is not due to an intestinal infection. The infection does not take place through the pancreatic duct, nor by simple contiguity, but is derived from the gall-bladder, as is proved by the successful treatment of the pancreatitis, which consists essentially in a disinfection or a removal of the gall-bladder. The infection travels from the gall-bladder through the efferent lymphatics of that organ, reaches a group of lymph nodes situated at the head of the pancreas, which in turn receive efferent lymphatics from the pancreas.

Diagnose und Therapie der Gonorrhoe beim Manne. Von Dr. S. Jessner, Königsberg, i. Pr. Würzburg. Curt Kabitzsch (A. Stuber), 1909.

Dr. Jessner's short treatise on gonorrhea forms part of his "Dermatological Lectures for Practitioners." It offers nothing actually new either in the diagnosis or the treatment of the disease considered, but presents the subject in a consrvative, attractive, and up-to-date manner. The latest additions to the list of silver compounds are duly considered, and all methods of treatment which interest the practitioner are given in detail.

Text-Book of Physiological Chemistry, in Thirty Lectures. By Emil Abderhalden, o. Professor für Physiologie des Physiologischen Instituts der Tierärztlichen Hochschule Berlin, und Universität-Professor. Translated by William T. Hall, Instructor in Chemistry, Massachusetts Institute of Technology, and George Defren. New York: John Wiley & Sons, 1908.

The translators of Abderhalden's book have rendered a very real service to the scientific professions of English-speaking countries; Abderhalden's lectures enjoy a great popularity in Germany and will probably meet with equal success in England and America. Of the thirty chapters, four are devoted to a consideration of the carbohydrates and six to the proteins. The chemistry of the inorganic foods, oxygen, animal oxidations, ferments, the blood and lymph are fully treated. The functions of the digestive organs and questions of general metabolism are discussed in the light of the most recent work in human and experimental physiology, that has modified so much the older ideas of these problems. The literary references have been selected with the design of offering to the student the most comprehensive and important original works and compilations. An index of authors and a subject index render the work very serviceable for reference. An interesting feature of the work consists in the last two chapters on the "outlook" of physiological-chemical investigations; these chapters are extremely suggestive and stimulating to the student of science.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, November 16, 1908.

THE PRESIDENT, DR. ROBERT T. MORRIS, IN THE CHAIR.

Asiatic Cholera.—Dr. WILLIAM H. THOMSON, in his paper on this subject, said there was no disease which illustrated more than did Asiatic cholera the wonderful progress in our generation of the knowledge in the medical profession regarding the infections, but it also must be admitted that nothing so illustrated the shortcomings of the profession in acquainting the public, by a proper terminology, of the difference between the three great classes of infectious diseases. The term "infectious" should include every disease caused by the entrance into and subsequent multiplication in the body of its own specific microorganism. Infectious diseases were divisible into three classes: First, that class in which the disease was communicated from the sick to the healthy directly, and in which mere proximity to the sick was sufficient to endanger those who were susceptible to the disease. To this class only should the term "contagious" be applied. The chief members of this class were smallpox, scarlet fever, measles, diphtheria, influenza, whooping cough, and typhus fever. Second, those which were communicated from the sick to the healthy, not directly, but indirectly, through some intermediate carrier. Prophylaxis or prevention of them, therefore, was secured by discovering what the intermediate carrier was, and then destroying the infecting agent. The chief members of this class were Asiatic cholera, typhoid fever, and tuberculosis. Third, those that were communicated only by inoculation through some puncture or wound or equivalent lesion of the skin or mucous membrane, and therefore they were not dangerous to bystanders, as the contagious diseases were. It was in this third class that the greatest triumphs of preventive medicine had been secured. They constituted the entire class of malarial infections by the bite of the mosquito; also yellow fever by the same means, and other very fatal maladies, such as the sleeping sickness of Africa, caused by the bite of the tsetse fly, the kala-azar of the East Indies, which was produced by the bite of bedbugs, and, finally, the bubonic plague, which was propagated to human beings by the bites of fleas which had bitten rats infected by the plague bacillus.

In the epidemic of Asiatic cholera in Hamburg in 1892, when the authorities found that one side of a street had many cases of cholera, if it was supplied by water from the Elbe, while the opposite side of the same street, which had a different water supply, did not have a case, they at once ordered scientific engineers to construct great sand filters to purify the Elbe water. On the completion of these filtering plants, cholera ceased, but not until ships infected with it had already sailed for New York. Its approach was heralded by the newspapers all over the country, and a widespread business panic took place which very seriously affected the commerce of the city of New York. This cholera scare gradually died out, and the city of New York to this day continued to drink unfiltered Croton water, with the results that thousands died here from typhoid fever, which, like cholera, was a waterborne disease, and which every year became more rife as the Croton ran low.

Notes on the Bacteriology of Cholera.—Dr. EDWARD K. DUNHAM made some remarks on this subject which he illustrated by means of lantern slide pictures. He said that in 1886 and 1887, while studying at the Hygienic Institute in Berlin under Robert Koch, he was enabled to compare a large number of cultures of the spirillum from epidemics in various parts of Europe, Egypt and South America, and it was then that he became familiar with the changes in physiological characteristics which this organism underwent with considerable rapidity. In culture media under laboratory conditions, the older the culture the further it departed from the type of recent cultures. In other words, there was a decadence in the character of the culture. During the cholera epidemic in 1892, the cases that occurred in this city were submitted to him for study, and a rather striking feature of the cases was that undess the dejecta were absolutely fresh, they failed to reveal the characteristic form of the organism in smears. It was impossible to make the diagnosis by a direct microscopical examination of the dejecta; yet if these dejecta were used for the preparation of plate cultures, one would obtain cultures containing only colonies of the cholera spirillum. The speaker then described in detail the method of making these cultures, and referred to the value of the nitroso-indol reaction. There were a number of other microorganisms which gave this reaction, the speaker said, but none, so far as he knew, that gave it so promptly and clearly as that of cholera. The more modern methods in the bacteriological study were agglutination and bacteriolysis, and depended on the action of certain immune sera, which could not always be had. For a bacteriological diagnosis from fresh dejecta, the direct microscopical examination, the rapid development in pepton solution, the appearance of colonies on gelatine plate cultures, the mobility, the appearance of gelatine stab cultures and the early nitroso-indol reaction, positive as soon as a pepton culture showed distinct cloudiness, due to growth —these data sufficed, in his opinion, to establish a positive diagnosis.

Cholera and Commerce.—Dr. WILLIAM T. JENKINS, formerly Health Officer of the Port of New York, read this paper, which dealt chiefly with the interference of both commerce and the liberty of passengers caused by regulations to prevent the advance of cholera. The following interesting and important facts regarding cholera were well known: Its place of departure was India, and its path on land corresponded to that of travel and traffic. Its trans-maritime advent corresponded with the track of commerce, and its visits to North America had been in cycles of about sixteen years. The last outbreak in America was in 1873, an interim outbreak, the explanation of which might be found, probably, in the arrival at New Orleans, where the epidemic entered on vessels from widely scattered ports. In 1887 two French steamers arrived at Quarantine with cholera aboard, but owing to prompt isolation and detention, the disease did not get any further. It was this appearance of cholera that caused the New York Academy of Medicine to appoint a committee, who, at the request of the Mayor, investigated the condition of the port and made recommendations for such improvements as would bring the Quarantine equipments up to the highest standard of modern scientific and medical knowledge. The result of its work, the speaker said, was the plant which he received from his predecessor in February, 1892. The next appearance of cholera in this port was in August and September, 1892, when it came from Hamburg. During the preceding February, fifteen cases of typhus fever had been discovered among some immigrants from Russia. This outbreak had put the Health Officer on the alert, and he notified all steamship companies of the necessity of detention, inspection, and disinfection of baggage at the ports of embarkation. It was this watchfulness that prevented an epidemic of cholera in this city seven months later. During the period from August 31 to September 15, 1892, six ships with cholera arrived, two of which carried cabin passengers, and in the cabin of each suspicious deaths had occurred. The total number of cases admitted to Swinburne Island was 72, and the percentage of deaths

was eleven. If a full knowledge of the hygienic condition of ship and passengers before sailing, at sea, and upon arrival was assured, and if on her arrival all were well, Dr. Jenkins said there was absolutely no danger of introducing cholera into the country, and therefore no reason for detention. Finally, not the least important feature in connection with this work was the promulgation and carrying into effect by the Secretary of State of regulations of inspection and detention at ports of embarkation, which were now in force and which, if properly observed, would arrest the march of any epidemic.

Dr. John B. Huber said that even before the time of Pasteur, who discussed Asiatic cholera and had a very good idea of it, Tyndall had declared that the disease must be the result of a germ, because if you sowed wheat you could not expect to reap barley, and just so the germs of smallpox or cholera could produce nothing else. In certain epidemics of cholera, fear seemed to have been a very potent factor, and in the recent outbreak in St. Petersburg, some of the soldiers who had all the symptoms of the disease failed to show the spirillum in the dejecta and were purely cases of psychological cholera.

Dr. George W. Nash of Hurley, N. Y., who was the New York Quarantine Medical Officer at Hamburg during the epidemic of cholera in 1892, said that when he arrived there the authorities had the situation pretty well in hand, and the principal thing was to guard against a recurrence of the epidemic during subsequent years. The method employed there for purifying the water was by sand filtration; the authorities were realizing strongly Koch's statement that the slower the water filtered, the less danger there was of contamination. In dealing with sanitation in small towns, the speaker referred to the difficulty of having anything done on account of the expense to the community.

Dr. Louis L. Seaman said he was in Paris during the cholera epidemic of 1892, and on account of the rigid censorship exercised by the authorities over the press, the people were kept in ignorance in regard to the real condition of affairs, and as a result there was little or no alarm or excitement. Some of the journals merely referred to the epidemic as mild cases of cholerine, although its severity might be judged by the fact that in one day he saw 151 bodies of persons who had died as the result of it. If the truth had been known, the hysterical conditions existing in New York might have been duplicated in Paris. As an example of the rapidity with which cholera did its work the speaker cited the case of a man who went to business in the morning apparently well; he was brought to the hospital at 10 o'clock, and at 4 o'clock that afternoon he was on the postmortem table. The speaker said he was in St. Petersburg about a month ago, and saw a number of cases of cholera during the outbreak there. The epidemic was handled very well by the authorities, considering the dense ignorance of the peasants and their unsanitary surroundings, and he also was of the opinion that it had been stamped out quite as quickly, probably, as it would have been in any city in the United States or anywhere else.

The President, Dr. Morris, said he tried to cross the Mediterranean on his way to Africa during the cholera epidemic of 1892, but the French officials were so active and took so many precautionary measures to prevent the spread of the disease that he had to return. There was no excitement and very little was said about it in the papers, but regulations were rigid.

Mr. Wolcott Beard spoke of the difficulties he had to contend with, and the opposition of the native witch doctors, in dealing, as Executive Officer, with an epidemic of cholera in the Philippines.

The discussion was continued by Drs. Ransford E. Van Gieson, A. Ernest Gallant, and J. Milton Mabbott, and was closed by Drs. Thomson and Dunham.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held November 12, 1908.

Dr. Godfrey R. Pisek in the Chair.

Presentation of a Case to Demonstrate the Tuberculin Reaction.—Dr. Henry Ewing Hale showed a child who had had inunctions with a 50 per cent. old Koch tuberculin in anhydrous lanolin on one side of the chest, and with a 50 per cent. Rockefeller tuberculin on the other. These applications were made two days previous, and were so typical that he said he wished to show them. The reaction consisted in the appearance of one or many red papules on more or less reddened bases.

Dr. Herman Schwarz said he had noticed that when the tuberculin salve was rubbed in on one side the reaction occasionally appeared on the other, and he advanced the theory that this reaction might be due to some reflex or neurotic condition which showed itself in some systemic reaction.

Dr. Godfrey R. Pisek called attention to some interesting observations that he had made on children who had been treated for diphtheria with antitoxin injections. These children were more prone to have dermatoses of all sorts, and they reacted more quickly to the tuberculin reactions. It had been his own experience that the Calmette eye test or the von Pirquet reaction could sometimes be obtained in suspected cases in which the Moro reaction was not obtained. But in those cases that gave histories of some previous skin affection a very quick, intense reaction was obtained from the Moro test in tuberculous children.

A Case of Spina Bifida.—Dr. Sara Welt-Kakels reported the case of a girl of three and one-half months whose family history was negative. There was no history of lues, though it was interesting that of nine pregnancies of the mother four were interrupted during the first half of gravidity. Of four childen born at full term two had died—one of pneumonia and the other of measles. The tumor was noticed at the time of birth, and had not grown perceptibly since that time. The child had been breast fed, thrived, and was never ill. The infant weighed 11¾ pounds, was pale, but fat, and there was no hydrocephalus. The child was very quiet, but moved the lower extremities as well as the upper ones. There was, however, paralysis of the sphincters of the bladder and rectum. Pressure on the distended bladder through the abdominal walls or through the rectum expelled the urine. In the sacral region was a tumor about the size of an orange, which was covered with normal skin. The skin was traversed by numerous small vessels; on the periphery was a fatty accumulation and a small pigmented area on the skin somewhat below the middle. The tumor was small, fluctuating, and transparent. It was not sensitive on pressure and no convulsions were thus elicited. On careful palpation the vertebral arches might be felt widely open. On pressing the tumor the tension of the large fontanelle was perceptibly increased. Dr. Kakels said that the prognosis in these cases was not good; that while the patient might reach middle life, on account of paralysis of the sphincters some inflammatory process of the urinary tract might sooner or later ensue, or, through the bursting of the sac, infection of the meningeal canal might occur. Cases had been reported, however, where after one or two burstings of the sac recovery had taken place. As regards treatment, the methods used were ligation of the sac or aspiration of the contents with the injection of some astringent.

Dr. William P. Northrup asked Dr. Welt-Kakels if there were any other malformations in the child presented.

Dr. Welt-Kakels replied that there were no other malformations either in the child she presented, or in other members of the family.

Dr. Northrup said that in many instances when such a malformation was met with there would be found others, and he recalled a patient seen recently with a similar tumor to the one presented by the little patient, but only about four-fifths the size, and which was to be operated on. Few of these cases recovered after operation. This child also had double club-feet. He recalled another patient with a hair lip, a complete spina bifida, and double club-feet.

Dr. Welt-Kakels reported another case, a boy, whom she had presented to the section some years ago. He had a spina bifida and incontinence of the bladder and rectum. He was six or seven years of age. An examination of the bladder was made to determine whether any stone was present or not, and forty-eight hours later the child developed a high temperature, with pyuria, and there appeared a large and tender right kidney. The kidney had to be opened and drained; later it was removed. For a time the child seemed to be doing better, but soon the temperature rose again, pus appeared in the urine, and uremia set in. She believed it was not wise to examine the bladders of such children through fear of causing a similar infection.

Obstinate Vomiting Cured by a New Method.—Dr. William P. Northrup read this paper. See Vol. 74, page 866.)

Dr. Thomas S. Southworth asked Dr. Northrup if the method had been tried of having the mother compress with two fingers behind the nipple to limit the rapidity of the flow of the milk.

Dr. Herman Schwarz asked if interrupted feeding had been tried, and whether the child vomited during or immediately after the nursing.

Dr. Ward Bryant Hoag asked if the child had been weighed before and after nursing to determine just how much milk he was getting.

Dr. J. Finley Bell thought that possibly Dr. Northrup got his idea from a study of the customs of the Indian squaws, who slung their babies over their shoulders, causing the babies to drink uphill.

Dr. Northrup said he had seen the infant but once. So far as he knew, the doctor in attendance had tried all the things he could think of. Weighing the baby before and after nursing showed that he was getting a little milk. Compressing behind the nipple with two fingers to limit the flow of milk he did not think had been tried. He could not say whether interrupted nursing had been tried or not. Vomiting came on almost immediately after the nursing. The stomach would become distended, and then the milk would immediately be expelled. As he stated in his paper, "the child took three ounces and vomited four ounces."

A Case of Ulcerative Endocarditis with Necropsy and Blood Findings.—Dr. Kaufman Schlivek reported the case of a girl three years of age whose family history was negative. She had had measles two months before her present illness, and since that time had been fretful. Her present illness began with cough and fever, the temperature ranging from 103° to 105°. There were frequent sweats, and the child complained of inability to stand or walk. Her bowels were at first normal, but during the second week of her illness she had four or five movements daily. Urination was normal. A physical examination revealed a fair general condition, though the child looked very sick; she was restless, breathed rapidly, and was somewhat cyanosed. The child lay on her right side, with her legs flexed on her thighs, and her thighs on her abdomen. The sensorium was clear. The tongue was coated and dry, the throat was red, and there was a slight general discrete enlargement of the lymph nodes. There were moist rales in both lungs, anteriorly and posteriorly, but there was good expansion at the bases. Examination of the heart showed the apex beat in the fifth space just below the nipple. The action was rapid, regular, and of fair force. There were no murmurs. The pulse was equal, rapid, regular, and of low tension. The abdomen was slightly distended, held very tense, generally tympanitic. Palpation was unsatisfactory, though no tenderness was revealed. There was liver dullness in the fifth space. The spleen was indistinctly palpable. The extremities were cyanosed and cold. There was right knee jerk, but no Kernig or Babinski sign. The left knee was tender and extension was painful. The white blood corpuscles numbered 27,000, and the differential count showed polynuclear neutrophiles 67 per cent. and lymphocytes 23 per cent. The urine was amber, clear, acid, with traces of albumen, but no sugar. There were a few hyaline casts and pus cells. Several diagnoses were made—bronchopneumonia, malaria, typhoid, rheumatism, and sepsis. For five days after her admission to the hospital there was very little change in her condition. Then petechiæ began to appear all over her body. Six c.c. of blood were taken from the forearm, plated in agar-agar and ascitic serum, glucose agar, glucose agar and ascitic serum. Each plate contained one and one-half c.c. of blood. The following day there was a growth on the several media, probably *Staphylococcus pyogenes aureus*. The diagnosis of sepsis was certain. The girl became worse, and the roughness of the first sound at the apex of the heart persisted. *Staphylococcus pyogenes aureus*, 35 colonies per c.c., were found in the blood cultures. The child continued to grow worse, and the first sound at the apex was replaced by a short, squeaking, musical murmur, which was heard over the entire precordium and for a short distance toward the axilla. This made the diagnosis septic endocarditis. Later in the day the murmur became faintly audible, the child developed pulmonary edema, and died. The treatment was stimulation, and for a few days sodium salicylate. Necropsy showed that the heart was not enlarged. The mitral valve had a pedunculated, verrucose vegetation, about the size of a large green pea, on the upper part of the anterior flap. There were two small ulcerations on this vegetation. On either side of the large vegetation was a small flat one. The lungs showed congestion and edema; the liver was enlarged and congested, and showed fatty degeneration. The kidneys were about the normal size and congested; the spleen was enlarged, congested, and showed numerous small grayish infarcts. *Staphylococcus pyogenes aureus* was cultivated. Dr. Schlivek had reported the case on account of the rarity of this condition and on account of the difficulty in diagnosis. Osler had found but three cases under ten years of age in a collection of 209 cases of malignant endocarditis. Dr. S. S. Adams had reviewed the literature of the past fifty years and had found but forty-seven cases in children under fourteen years of age.

Dr. William P. Northrup said that after his autopsy work of many years at the New York Foundling Asylum he knew of but one case of this kind. The report of this case and the specimen had already appeared in the transactions of the Pathological Society.

Dr. Herman Schwarz said that at the Mt. Sinai Hospital during the past six years there appeared two such cases, one a child of seven, the other a child of ten years.

Dr. Sidney V. Haas reported a case of ulcerative endocarditis occurring in a boy of seven or eight years. He had two pus kidneys and a gonorrheal endocarditis. A pure culture of the gonococcus was obtained.

Tics and Their Treatment.—Dr. E. W. Scripture read this paper and presented a number of patients to

illustrate it. He first showed a patient who screwed his mouth around to the left side. This was a movement that might have been made for a definite purpose by a group of voluntary muscles, but the movement was made unconsciously in some instances; in this case the patient said he made the movement whenever he thought of it. The most usual tics were those of the eyelids, the snorting tic, the sucking tic, the surprise tic of the forehead, the frowning tic, the grimacing tic, the scalp tic, various tics of the ear muscles, several tics of the chin, the licking and clicking tics of the tongue, several varieties of masticating tics, various tics of the neck, including torticollis, tics of the shoulders, arms, legs, etc. There were also coughing, spitting, swallowing, eructation, vomiting and respiratory tics. In some cases it was possible to trace the origin of the tic, as, for instance, in one patient who had a speck of dust in his eye, and after the speck was removed he had continued to shut his eye tightly. He had known other cases where the snort probably had its origin in the effort to clear the nose. The nasal obstruction was removed,, but the snort remained. No one had been able to tell why these movements persisted. They appeared to be related to the obsessions so common in childhood, as where the person felt compelled to touch every post he passed or to avoid the cracks in the sidewalk. The person affected by a tic could, by an effort, refrain from the movement, but in most cases he had to seek a favorable opportunity, when no one was looking, and perform an extra number of movements. Some of those who were subject to the tic were of a neurasthenic disposition. Some neurasthenic children became stutterers, and others were affected by tics. In the neurasthenic, peripheral irritation was among the various causes that produced tics. Chorea furnished a large number of "tickers." In these cases the irritation might be peripheral or central. Some children acquired tics by imitating others. Some tics might arise from emotional disturbances. These tics developed on a hysterical basis. The tic was distinguished from normal movements by the lack of an adequate cause. Where there was an adequate cause the movement was not a tic, as, for example, a child with a snorting tic was found to possess a large polyp in the nose; when the polyp was removed the movement ceased. This was, therefore, not a tic. The tic was distinguished from the spasm by its mental character. A spasm involved only the spinal reflex arc; it was not modified by attention, distraction, or emotion, and usually affected the muscles supplied by a single nerve. It was not preceded by a feeling of compulsion or followed by a feeling of relief. If the convulsive movement continued during sleep it was a spasm; if not, it was a tic. He had had a severe case of torticollis which had been repeatedly operated upon; the movement ceased during hypnotic sleep. The tic was distinguished from chorea by the systematic nature of its movements and the relatively longer pauses. In paramyoclonus multiplex the cramps occurred in single muscles, and there were other differences. The term stereotype movements or "habit spasms" should be reserved for movements that did not differ in their form from normal movements; the convulsive character was lacking. He thought the spasmodic movements found in cases of hysteria were genuine tics. The tic of the neurasthenic was often benefited by tonic treatment. The tic due to hysterical conditions demanded treatment aimed at the mental condition. One method of treatment that he had found very effective was conscious repetition. The patient was told to hold a mirror before himself and to watch for the tic, and when he saw it he was to repeat it five times voluntarily. His first attempts to imitate himself were often ludicrously inadequate. He was made to persist in the effort to imitate himself exactly until the movement was entirely under his control. The failure of the imitation was especially marked when the tics were unconscious. The patient was advised to voluntarily repeat the movement every time he caught himself making it. He explained this treatment as follows: The tic was carried out by mental activity of less than full consciousness; the act might have become entirely subconscious. Perfect voluntary imitation of the act trained the mind to doing exactly the same act consciously, and thereafter the act was no longer an involuntary subconscious one, but a voluntary conscious act.

Dr. Charles Herrman said there was no adequate provision made for the treatment of stammerers and stutterers, and there should be in every clinic some department for the special care of these cases. Their number was large. From what he had seen, there was a decided association between stammering and stuttering and tics. The most common tic was that of the eyes. Mental torticollis was a tic they should recognize more often; this was a tic that was not due to rheumatism or other causes usually given. Many of these cases were operated on unsuccessfully. He said he had found in the history of these mental tics a distinct neurotic family taint, and in addition there often appeared night terrors or enuresis. These neuroses might appear either in the patients with tics, or in other members of the family. An important differential point between tics and chorea was that the tic was repeated in the same place in the same manner; in chorea there was no telling where the next twitch would be.

Dr. L. E. La Fétra said he had seen many of these cases at the Vanderbilt Clinic and had sent them to Dr. Scripture's class in the same institution. The results obtained were most gratifying.

Dr. B. Onuf spoke of the difficulties attending the differential diagnosis between tics and athetosis. Frequently chorea had its starting point in these tics. Often there was associated a mental tic with the physical one, *e.g.* an impulse might arise while one was talking to depart from the topic of conversation and speak of lamps, watches, etc., and so the patient would be unable to carry on a connected conversation. In these patients it was very important that they should be subjected to a system of education; they must learn to control their actions and their will. It was often necessary to remove them from their usual surroundings.

Dr. Charles E. Atwood said that the hydrotherapeutic treatment in connection with the treatment advocated and carried on by Dr. Scripture was very beneficial. Electricity was used as well, applying faradism to the opposing muscles and galvanism to the affected muscles.

Dr. Louis C. Ager asked if there were any grounds for supposing that the method of introducing cadence and rhythm into the voice changed in any way the reflex cerebral arc, or whether it was simply a form of self-hypnosis.

Dr. Herman Schwarz asked if there was any difference between stuttering and stammering.

Dr. Henry Heiman said it was often very difficult to differentiate these tics from chorea, and one of the methods used at the clinic was to have the patient protrude the tongue; in chorea one of the first symptoms was the occurrence of the choreic movements of that organ.

Dr. Scripture said he was glad to note the readiness with which the people took up his idea, and above all the will power displayed to carry it out. Anywhere from one-third to one-half the stutterers could be cured by the general practitioner if they would devote a little attention to the method employed. One per cent. of the entire population stuttered. There was no real difference between stuttering and stammering; in the former the same syllable was repeated over and over again; in the latter cramps were present. Patients with complicated tics

should be taught to move gracefully and to assume graceful attitudes.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 27, 1908.

DR. W. S. STONE IN THE CHAIR.

Vesicovaginal Fistula Following Abortion in an Operated Case of Incomplete Congenital Transverse Septum of the Vagina.—Dr. SAMUEL M. BRICKNER reported the history of a woman, 24 years old, who was admitted to Mt. Sinai Hospital in July, 1907. Her menses began at the age of 13, and a doctor made a puncture to allow the menstrual flow and blood to escape. The flow had always been regular, of three days' duration, moderately profuse, and accompanied with no pain. She had been married eleven months, but was never pregnant. Coitus was very painful. On examination the urethra and outlet were found normal, but the vagina ended about one and a half inches from the vulva. At the internal end a pin-hole opening and a mucous discharge could be seen. The rectal examination revealed a small, retroverted, movable uterus, and a boggy mass over the cervix and septum. This was evidently the vagina filled with secretion. The appendages were not felt, and her condition was otherwise negative. A cross-shaped incision was made through the minute opening, which was situated a little to the left in the upper left quadrant of the septum. This incision was extended to the right, left, and downward. It could not be extended upward, because the posterior wall of the septum was tightly adherent to the cervix. This was bluntly dissected away from the cervix. The septum was then completely excised circularly, the cervix being well exposed and a piece of gauze inserted into it. The cervix was infantile in size and shape. The septum was extremely thick, its base occupying practically the entire floor of the vagina. A continuous suture was passed through the cut edges, no mucous membrane being available for the upper part of the posterior wall. The vagina was then tightly packed with gauze. The specimen was covered by squamous epithelium. Within the next few days the gauze was removed and reinserted several times. Later glass plugs were used, which the patient was taught to remove, clean, and reinsert daily. When she was discharged the vagina could easily admit a large glass plug. The walls were thick and lined with mucous membrane. She was told to clean and reinsert the plug daily; but when she returned for inspection it was learned that she had not worn it regularly, and that considerable contraction of the vagina had taken place. She passed from observation from September, 1907, until she returned in October, 1908. She stated that she had become pregnant last spring, and at four and a half months had entered the Lying-in Hospital, where she aborted and was curetted. After leaving the hospital she observed that she lacked urinary control. At first she had incontinence during the day only, but later it continued both day and night. The urine dribbled continuously, more when she stood or walked than when sitting or lying, but it never stopped altogether. The second examination showed a vagina about two inches deep. The upper vault was rounded off, and in its summit was a small orifice from which urine leaked and entered directly into the bladder. The cervix could not be seen, but in the middle third of the vagina was a small orifice through which a probe could be passed for two and a half inches, evidently into the uterus. The uterine body could be felt anteriorly. A vaginal septum consisting of scar tissue occupied the vagina transversely. On October 24 the septum was incised transversely between the fistulous opening and the orifice leading to the cervical canal, exposing the cervix and the fistula, which was one-half an inch long, and one-quarter of an inch wide. The cervix was seized with bullet forceps, and the edges of the fistula were freshened. The bladder mucosa was separated from the muscularis, the bladder mucosa inverted, and sutured with interrupted chromic gut sutures. The overlying tissues were also sutured with chromic gut, and a permanent catheter inserted. Four days later the catheter was draining well. On the eleventh it was removed, the bladder was irrigated, the return flow being clear. On November 12, eighteen days after the second operation, the vagina was seen to be filled with scar tissue. The patient urinated about every three to five hours. A small opening into the uterus still remained. The fistula was closed. The following were the features of interest in this case: First, in the pregnancy following the operation for the relief of the septum; secondly, in the difficulty of delivering even a four and a half months fetus; thirdly, in the complete subsequent scarification of the vagina; and fourthly, in the origin of the septum. The origin of congenital transverse septa was of great embryological interest, and Dr. Brickner had shown in a former paper that they were normal in adult sheep, whales, dugongs, the manatee and the chimpanzee. When they occurred in the human female, they might represent return to an ancestral type. Their function was purely speculative, but might have to do with the facilitation of conception; and when they appeared in the human being they might have the same purpose, to aid in overcoming other minor defects of development.

Dr. BROOKS H. WELLS said that he had seen two instances in which transverse septa occupied the lower end of the vagina. In all congenital cases these transverse septa occurred because the lower end of the Müllerian duct had not opened. The lower end of this tube had not become absorbed, resulting in these septa. Dr. Wells said he had seen these septa lying in what appeared to be a normal hymen. In this case, however, there was a mass of cicatricial tissue caused in all probability by diseases of childhood.

Dr. H. N. VINEBERG, after examining the patient, said that she had a very shallow vagina and with a mass of cicatricial tissue in its upper part. No cervix could be felt.

Unusual Absence of Peritoneal Adhesions After Severe Septic Infection.—Dr. LE ROY BROUN reported this case. The patient was married, twenty-eight years old, and never had a miscarriage or children. Six weeks ago she was two months pregnant, and had an abortion performed. Two weeks after this she began to have pain in the abdomen and back. She had a foul discharge, and this was attended with repeated chills and fever. Before entering the hospital she was curetted by her attending physician. On admission her pulse was hardly perceptible and numbered 120; her temperature was 102°, respirations 30. Her abdomen was distended with a hard inflammatory mass reaching to the umbilicus. The vault of the vagina was filled with an inflammatory exudate, and the uterus could not be made out. The patient was kept under observation for one week, after which the mass became more tense anteriorly. On January 21, eight days after her admission, an incision was made in the anterior cul-de-sac and a large amount of broken-down blood and pus was evacuated. Drainage was introduced and the extent of the abdominal exudate rapidly diminished, with corresponding physical improvement. At different times, and through the same anterior incision, punctures and drainage were made in other pus pockets. The smears from these discharges showed median-sized cocci, growing in chains. There were many pus cells. On March 5 incision and drainage through the posterior cul-de-sac liberated a quantity of pus of the same character as on former occasions. The anterior vaginal incisions ceased to discharge and

closed, the posterior refusing to heal. After two months of expectant treatment she was readmitted to the hospital, May 20, for abdominal section. The uterus was small and in good position. To the left of the uterus was an inflammatory mass, probably ovarian in origin, which was connected with the opening in the posterior cul-de-sac. On May 21 an abdominal section was made and dense adhesions were anticipated, but a remarkable absence of such condition was found. The left ovary and tube were embedded in adhesions which were easily severed. The ovary was the seat of an old abscess, and the abscess cavity communicated with the cul-de-sac opening. The tube of this side was thickened. The abscess, together with the tube, was removed and drainage instituted. The recovery was even. The presence of many adhesions was anticipated after such an extensive and severe infection. The failure to find them was striking, their existence being chiefly limited to the area of the infected left tube and ovary.

Abdominal Sections for Removal of Pathological Conditions Following Former Conserving of Parts in First Operations.—Dr. BROUN also reported these cases. The first patient was a woman, 39 years old, with a large ventral hernia in the line of a former laparotomy scar. An ovarian cyst, 8 or 10 cm. in diameter, was to the left of the cervix. The pelvic adhesions were very dense. The uterus had been amputated at a previous operation. The woman said that a myomectomy had been done in 1903, and a supravaginal hysterectomy in 1906. At operation the pelvic adhesions were found to be unusually dense and abundant. One ovary had been removed; the remaining ovary was the seat of a unilateral cyst of the type of a distended Graafian follicle. There was much oozing from raw surfaces. The ventral hernia was repaired and the recovery was uninterrupted. Another patient had a multiple fibromyoma of the uterus with hemorrhages. A supravaginal hysterectomy was done. One ovary was removed. About one year later an ovarian cyst developed; this was removed. The character of the cyst was unilocular and had the appearance of an enormously distended Graafian follicle. These two cases suggested to Dr. Broun a common cause for their occurrence, an obstruction in the return circulation. They were not true adenocystoma; they were all enormously distended Graafian follicles and could readily be caused by the disturbance in the return circulation of the ovary, such as necessarily followed a hysterectomy.

Dr. H. N. VINEBERG said that the first case was another illustration of the fact that there was a class of cases gynecologists were not treating in the right way. He knew cases of pus collections in the abdomen treated by methods that prevailed ten years ago. They should be able to attack these cases with pus in the abdomen with as little risk to the patient as in cases of appendicitis; they should not make one puncture after another through the vagina and let the patient go on for months and then be compelled to open the abdomen and find a simple condition to deal with. In the treatment of such cases he did not believe they were up to date. The next advance in gynecology would be in the direction of the proper treatment of these cases. Conservative work must go on, but a suitable class of patients must be first obtained.

Dr. J. O. POLAK said that the conditions found in the first case reported by Dr. Broun showed, to his mind, an extreme conservatism on the part of nature: in the exudative cases was to be found nature's protection, and these were the cases that could be handled better by the vaginal than by the abdominal route. In cases of general septic peritonitis he could do more by a radical procedure; but in the exudative cases nature had a way of protecting the peritoneum by an exudate; and this could be tapped better by vagina.

Dr. CLARENCE C. SICHEL said he has had three cases in which the intestines and uterus were bound down with dense adhesions, and he thought that such cases could be better attacked by way of the abdomen. They were dealing with pus, and even if drainage must be subsequently employed through the cul-de-sac, a better recovery was made than when an opening was made in the vagina alone.

An Analysis of Eighty Consecutive Cases of Ectopic Gestation.—Dr. ROBERT T. FRANK read this paper, which was based upon the records of eighty unselected consecutive cases of ectopic gestation, admitted to Mt. Sinai Hospital from 1902 to 1908. Most of the cases were found in the active child-bearing period. Sterility appeared to have but slight importance as an etiological factor, only six women being sterile, and ten not having had children within four years preceding the ectopic. There were several women who had been married less than six months. Exactly one-half of the women did not skip a menstrual period. Spotting, however, either alone or alternating with profuse flow, occurred in fully 72 per cent. of the cases. Pain was rarely absent, and in more than one-half the cases it was unilateral and well localized. Patients in collapse had a small, very rapid pulse, sometimes not perceptible at the wrist. The physical examination with few exceptions demonstrated enlargement of the uterus. In 86 per cent. of the patients a boggy, tender mass was noted to the side of, or behind, the uterus. Fainting occurred in 32 per cent. of the cases. The blood count and the hemoglobin percentage proved of no special diagnostic value. Of the symptoms a history of spotting, cramplike pains, especially if localized, and attacks of faintness were of most significance. The rapid pulse rate, pallor, and a mass in the vicinity of the uterus, in connection with the above subjective signs, clinched the diagnosis. Of the eighty cases, all but three were subjected to operation. There were 42 ruptures, 21 on the right, and 8 on the left side; there were 20 abortions, 12 on the right, and 8 on the left side; there were 11 hematoceles, 4 unruptured, 1 intraligamentous rupture, 1 abdominal, and 1 ectopic with intrauterine. Exactly one-half the ruptured tubes were operated upon at once, but only two of the 20 cases of tubal abortion required immediate intervention. The conditions discovered after opening the abdomen corresponded closely to the clinical signs. In 37 cases of the series free blood without tendency to encapsulation was encountered. There were 77 recoveries and three deaths, a mortality of 3.75 per cent. Of these 80 cases at least eight were curetted, ectopic gestation not having been recognized. Were they all able to judge the exact merits and the urgency of the condition which confronted them, he believed that all doubtless would operate in haste less frequently.

In hospital practice, the speaker said, the following appeared to him to be the best method to pursue: (1) Before all else the diagnosis must be assured. Patients who gave a history suspicious of ectopic pregnancy, and in whom the uterus did not show the shape and size corresponding to their supposed period of gravidity, or who had a mass near the uterus, should be consigned to a hospital, or should be kept under the closest observation at their homes. (2) Such patients should never be subjected to forcible examinations, nor should they be curetted until every possibility of ectopic had been definitely excluded. (3) If after two or three days of observation the condition had not definitely improved and no marked tendency to hematocele formation had developed, laparotomy was indicated. Should severe attacks of pain, fainting, or collapse ensue during this period of waiting, operate at once. Where a hematocele was still small or ill-defined, laporotomy would shorten the period of convalescence. In well-defined hematoceles, vaginal section for evacuation and drainage would suffice.

(4) If a patient, when first seen, was in a precarious condition, it was safer to err on the side of early operation than to wait. (5) When a patient was seen in extreme collapse, immediate rapid laparotomy, with subsequent measures to combat both the hemorrhage and the shock, was indicated. That inexperienced diagnosticians were deceived and failed to distinguish between transitory primary shock and real grave hemorrhage was doubtless true, but he said he would prefer to have them interfere unnecessarily early rather than to wait. Whether the future advance in differential diagnosis between hemorrhage and shock would enable the surgeon to recognize the anatomical conditions before operation was a matter of pure speculation. At present the earmarks which constituted the small class of extreme cases would naturally remain an open question, but indications would vary with the experience of each individual gynecologist.

Dr. Brooks H. Wells said that this controversy as to the merits of deferred or immediate operation in cases of ectopic gestation reminded one in many ways of the old story of the two knights who fought over the question of the metal of the shield hanging by the wayside. They who had traveled the road many times should remember the gold of the one side, as well as the silver of the other. A woman with an ectopic pregnancy was in serious danger, danger so great that the highest duty of her physician was to keep always the possibility of its occurrence in mind and so be ready to recognize the first red flag held up by nature, the slight unusual menstrual irregularity and the slight unusual pelvic pain. It was ideal to make the diagnosis and remove the cause before rupture had occurred. It was good surgery to operate in all cases as soon as a proper environment and the necessary skill could be secured.

There was only one possible exception to this, when the patient was in desperate collapse from sudden hemorrhage. This question, as it appeared to him, would never be settled by academic discussion. It was one that must always be largely influenced by the personal equation of the surgeon in charge; by the facts of his individual experience, judgment, and skill, and he would be the safest man who proceeded deliberately. Yet he who refused operation because of alarming conditions could not by so doing shift his responsibility in the event of the patient's death. He had twice seen women with ruptured ectopic pregnancy allowed to die because the surgeons in charge would not operate until reaction occurred, and he knew with certainty of many other instances where the same men had followed the same waiting plan. With these facts in mind it became impossible for him to believe that women with ruptured ectopic pregnancy might not die, even if certain men had stated that they had not seen patients die, or had not lost patients by waiting, or if another might claim that bitches with cut pelvic arteries recovered.

Dr. Wells said that his own inclination to operate was strengthened by the fact that out of a large number of ectopic cases he had operated upon eight during dangerous collapse and they, as well as all the others, had recovered. His own rule was in cases with dangerous collapse to operate as soon as possible when some improvement was shown during the time of waiting for necessary preparation. He advised keeping the patient on the table, the use of light ether-oxygen anesthesia, a moderate Trendelenberg's position, operate quickly, tying the tube, scooping out the clots that were easily reached, closing the abdomen, give hot salt solutions by rectum, and expect the patient to get well. The benefits of a long delay before operation, a delay of from one to several weeks, so that the patient's general condition might improve, had been strongly urged by some recent papers. In the long-delayed cases one had not alone the primary mortality to consider, but also the increased morbidity following long delay. In his own experience the cases that had caused the greatest anxiety had been delayed operation with sepsis, not due to operation, but to serious intrapelvic conditions found at operation. Operation performed before rupture, or before serious bleeding had occurred, was not ordinarily difficult for anyone skilled in this class of surgery, and should be followed by almost no mortality. Operation delayed for several weeks meant complications with added danger from adhesions and often pus and sepsis from the ruptured tube. Dr. Wells said that he did not place much reliance on the strictly mathematical or statistical factors of an argument in a question like this yet, as it was admitted that about 95 per cent. of the cases of ectopic pregnancy with bleeding would not die immediately from hemorrhage, one might hold that when one could show a mortality of any two or three per cent. in his general abdominal and pelvic operations, he could be safely trusted to use proper care and judgment and to operate upon a ruptured ectopic at any time he thought wise. If, on the other hand, the mortality ran up to more than five per cent. it seemed equally evident that in the long run that the surgeon who had such mortality among his cases would gain nothing by immediate operation. This brought the argument back again to the personal equation of the surgeon in charge.

Dr. Le Roy Broun said there was a decided difference in the structure of an artery of a dog and of a human being. Robb's position was based upon the failure of a bitch to bleed to death after the artery had been severed. The internal coat of a dog's artery differed from that of a human being in that there was a more elastic condition of the longitudinal fibers; when such an artery was cut this elastic coat would cause the artery to retract and in consequence of this retraction the bleeding would naturally cease.

Dr. Joseph Brettauer considered the question of deferred or immediate operation. He said that in those cases which were serious, such as hemorrhage, where the woman was *in extremis,* it was best to operate. This question might be considered in those cases where it did not matter what was done—the patients would get well with or without operation. In the milder cases where the pulse was not much increased in frequency and the signs of acute hemorrhage were not marked, the question arose, should one operate, or should one wait? In the last two years Dr. Brettauer said he had been satisfied and gratified at the results of operating; the sooner one operated the better, and the more chance the patient would have to get well.

Dr. Philander A. Harris said that he had operated upon 154 cases of tubal pregnancy, and in not a single case had death followed operation which was accepted by the patient, at the time he proposed it, in any of the cases exhibiting the so-called familiar condition known as shock. There were two deaths and these two patients represented "deferred opration." The remaining cases, 152 in number, he placed in another class, in that operation was never deferred after it was advised for the patients and accepted by them. Among these 152 cases he had four deaths, but in not a single instance did a patient die who was operated upon in a condition of shock, and there were many such. The four deaths resulted from sepsis.

Dr. H. N. Vineberg said he was surprised at the number of cases in which there was no absence of menstruation; Dr. Frank's figure in this respect was larger than his. There were only ten out of eighty patients that had not skipped a menstrual period. The sooner operation was performed upon this class of sufferers from ectopic gestation the better was the chance for recovery which these patients would have.

Philadelphia Neurological Society.

At a stated meeting held November 27 Dr. Wm. G. Spiller presented "A Case of Facial Spasm Treated by Alcoholic Injection." The patient was a man, about thirty-five years old, in whom violent facial spasm had been present for many years and had resisted all ordinary forms of treatment. An incision was made in the mastoid region on the affected side, the nerve exposed, and an injection of alcohol made into the trunk of the nerve. The spasm ceased immediately and facial palsy resulted. This soon began to improve and it has now entirely disappeared. Dr. Spiller then showed "A Case of Facial Palsy Associated with Exophthalmus on the Same Side" in a girl, thirteen years old, who, following a convulsion at the age of three, presented the symptoms mentioned, and which had persisted without change. The eyegrounds exhibited no abnormality. No satisfactory explanation for the condition was at hand. Dr. Spiller referred to a second case, in a woman, with facial palsy, who related that at the onset of her disorder the affected side of the face had been swollen and the eye on that side had protruded. Dr. Alfred Gordon demonstrated a patient exhibiting "The Cerebellar Syndrome Showing Progressive Improvement after a Decompressing Operation." The patient was a colored man, forty-one years old, who presented symptoms of a cerebellar growth, with bilateral choked disk and marked impairment of vision. Trephining openings in the skull were made in the occipital region on each side, with marked improvement in the symptoms, but with the development of vertigo when the patient turned the head to the side opposite that of the lesion or on awaking after lying on the side designated. Dr. W. J. McConnell reported "A Case Presenting Symptoms of Bilateral Motor Tract Disease, with Dissociation-anesthesia." The patient was a man with a syphilitic history, who presented paresis on one side of the lower part of the body and loss of the various forms of sensibility on the opposite side. Improvement ensued under vigorous antisyphilitic treatment. Dr. C. K. Mills presented "A Case with the Symptom-complex of a Lesion of the Upper Part of the Anterior Spinal Arteries (Spiller's Syndrome)." The patient was a woman who, in apparently perfect health, was suddenly overtaken by an apoplectic seizure, from which she recovered with slight but not aphasic disturbances of speech and weakness in all four extremities. The paresis in the lower extremities disappeared, while that in the upper persisted, and apparently was attended with wrist-drop and wasting. Dr. Mills also presented a communication entitled "A New Symptom-complex, Flaccid Paralysis or Extreme Hypotonia of the Muscles which Poise and Support the Head." In illustration of this symptom-group he recited two cases of brain tumor, in one of which, occurring in an adult male, autopsy disclosed the presence of a subcortical tumor in the frontal region and involving a portion of the corpus callosum. In the second case, the symptoms pointed to a cerebellar new-growth but no autopsy could be secured. Dr. Wm. G. Spiller read a paper entitled "The Duration of Life after Extensive Hemorrhage of the Brain." He presented evidence to show that life is, as a rule, prolonged for some hours after even extensive and destructive cerebral hemorrhage, indicating that almost instant death must be attributed to other causes. Dr. Wm. J. Dugan read a paper entitled "The Uses of High Frequency Currents in Neurology." Among other things, he had found the current useful in inducing sleep and in relieving the pains of locomotor ataxia, but contraindicated in cases of hysteria. Dr. S. Leopold presented a communication entitled "Sacral Tabes: A Case with Necropsy." In addition to classic symptoms of posterior sclerosis there was preservation of knee-jerks with loss of Achilles tendon jerks.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

South Carolina State Board of Medical Examiners.

Columbia, June 9, to and 11, 1908.

GENERAL ANATOMY.

1. Name the bones of the head.
2. Name the bones of the lower extremity.
3. Name the muscles of the abdomen—deep and superficial.
4. What chief arteries supply the neck and head?
5. Where are the epigastric arteries found? Branches of what arteries?

REGIONAL OR SURGICAL ANATOMY.

1. In the lymphatics of the peritoneum, which are most rapid in absorption, those of the diaphragm or of the pelvis? If you wish to stimulate in abdominal incision, what position would you place the patient in? If to retard too rapid absorption of pus in cavity, what position?
2. What are the anatomical points to be remembered in paracentesis thoracis?
3. From its anatomical position, why is rupture of the kidney of less danger than rupture of the liver and the spleen?
4. A case presented with apparent dislocation with atrophy of shoulder muscles and arm, only partial motion. What anatomical points would decide between dislocation of the shoulder and paralysis of the deltoid?
5. What nerve supplies the superior oblique muscle of the eye, and what defect of vision would you have in paralysis of the same? What nerve supplies the external rectus; what would you find in paralysis of that muscle?
6. What is the most common point of fracture of the humerus? What are some of the sequelæ?
7. Give surface marking of the brachial artery.
8. Give surface marking of the femoral artery (common and superficial); where best compressed? Where best ligated?
9. In lateral lithotomy, name anatomical points to be avoided.
10. Give the anatomical position of the deep epigastric artery to direct and indirect hernia.

PHYSIOLOGY.

1. What conditions hasten or retard the coagulation of blood, and mention the physical properties of the blood?
2. What produces the second sound of the heart, where best heard, and what events in the heart's action are coincident with it?
3. What is the difference between warm and cold blooded animals, and how is heat produced and disseminated from the body?
4. How is the secretion of glands chiefly regulated, and how do the kidneys secrete urine?
5. What results would follow a complete division of the right facial nerve?

CHEMISTRY.

1. Give chemical formula for common salt; nitrate of silver; sulphuric acid; nitric acid; water.
2. What is the difference between blue mass, mercurial ointment, and citrine ointment?
3. What is gray powder?
4. What is the difference between static and galvanic electricity? Give methods of production.
5. What are the positive and negative poles of a battery termed?

PRACTICAL URANALYSIS, MICROSCOPY TOXICOLOGY

1. How do you make a chemical analysis of the urine for life insurance?
2. Give indications of high and low specific gravity in the twenty-four hour urine.
3. What does transitory low specific gravity indicate?
4. Give differential morphology of blood, pus, oil and water under the microscope.
5. Describe simple and compound microscopes.
6. What oculars and objectives are in common use?
7. Give symptoms and antidotes to poisoning by sulphate of atropine.
8. Give symptoms and antidotes to poisoning by opium.
9. How would you detect a case of poisoning with carbolic acid or potassium hydrate?
10. What fumes are given off by arsenic when it is burned?

MATERIA MEDICA.

Give the dose and physiological effect of:

1. Fluid extract of ergot
2. Sulphate of sparteine

3. Veratrum viride.
4. Chloral hydrate.
5. Tincture of digitalis.

THERAPEUTICS.

In treating the following diseases, give dose, frequency of administration and physiological effect of drugs used; also other remedial measures used, giving physiological effect and mode of use:

1. Acute articular rheumatism.
2. Acute lobar or croupous pneumonia.
3. Erysipelas.
4. Dysentery.
5. Enterocolitis of children.
6. Dysmenorrhea.
7. Orchitis (non-specific).
8. Acute nephritis.
9. Acute gastritis.
10. Gastric ulcer.

BACTERIOLOGY AND PATHOLOGY.

1. What is meant by aërobic bacteria? What is meant by anaërobic bacteria?
2. Name three most important culture media.
3. State briefly the morbid anatomy of catarrhal appendicitis.
4. What connection has typhoid fever with the formation of gallstones?
5. Differentiate between fatty degeneration and fatty infiltration.

PRACTICE OF MEDICINE AND DISEASES OF CHILDREN

1. Differentiate simple melancholia and hypochondria.
2. (a) What are the causes of cardiac arrhythmia? (b) Symptoms and treatment of angina pectoris?
3. (a) What are the possible sequelæ of pneumonia? (b) What symptoms would cause you to suspect incipient pulmonary tuberculosis?
4. Mention the causes of anemia.
5. Symptoms of interstitial nephritis.
6. Symptoms and treatment of acute dysentery.
7. Make diagnosis and give reasons from following history and symptoms:

J. S., aged 40 years. He had suffered for years with indigestion, and for several months with pain in epigastrium, which was relieved by eating, and for one week remained in bed on account of aggravation of epigastric pain. At 1 o'clock in the day got up and went to the back door to look out. While there was seized with sudden severe pain in abdomen. He vomited and crawled back to bed. At 3 P.M. his pulse was 90, temperature 101 degrees F., abdomen of board-like rigidity, tenderness everywhere, but more tender in epigastrium. He was given morphine, gr. ¼. At 9 P.M. he was somewhat improved, and his muscular spasm was a little less. At 11 P.M. was pale and looked sick. There was distinct spasm and tenderness in epigastrium, shading off into other regions of abdomen, which was generally retracted. There was no dullness. Tongue moist. Pulse 90, temperature 101 degrees F.

8. Symptoms and sequelæ of scarlet fever.
9. What per cent. of fat and proteids would you prescribe for a child four months old? How would you direct the mother to make it?
10. Causes of convulsions in children? Causes of vomiting in children?

OBSTETRICS AND DISEASES OF WOMEN.

1. With what conditions may pregnancy be confounded?
2. (a) How does placenta prævia develop? (b) Where does the hemorrhage come from that endangers the mother's life? (c) In what way is the child's life endangered in this condition? (d) How would you treat a case of placenta prævia when hemorrhage occurs prior to full term?
3. How would you treat a case of postpartum hemorrhage?
4. What are the prodromal symptoms of eclampsia, and what would you do to prevent it?
5. How would you treat a case of prolapse of the arm in a transverse position?
6. How would you treat a case of retained placenta?
7. Under what conditions is a physician justified in inducing premature labor?
8. What symptoms and conditions would cause you to suspect twin pregnancy?
9. How would you perform a curettage after an incomplete abortion?
10. What are the ultimate dangers from gonorrhea in the female?

SURGERY.

1. Causes which retard, interfere with, or prevent a wound from healing; (1) in wound itself; (2) in subject of wound; (3) in treatment.
2. To promote the primary union of a wound, name six important factors.
3. When a visible part is inflamed, there are four notable phenomena to be observed; what are they?
4. (1) What causes bedsores? (2) How would you prevent them? (3) When present, how would you treat them?
5. Acute orchitis: (1) Etiology; (2) symptoms; (3) treatment.
6. How would you treat chronic ulcer of the leg?
7. Give symptoms and treatment in downward dislocation of the head of the humerus.
8. How would you treat a simple fracture of the middle third of the femur?
9. Necrosis of the lower third of femur in a boy of twelve years. Give early symptoms and treatment.
10. In amputating the lower third of the leg, give the several steps of the operation, including dressing.

PRACTICAL HYGIENE, SANITARY SCIENCE, STATE MEDICINE.

1. State the period of incubation and contagion in scarlet fever, diphtheria, pertussis, measles, rubella, smallpox, typhoid fever, parotitis.
2. What hygienic care should be taken by pregnant and parturient women?
3. What condition would cause you to condemn meat, and what would you do to insure milk from impurities, that is, milk meant for the public?
4. What infectious diseases may be conveyed through the medium of air, water and food, respectively?
5. What are the injurious effects of excessive use of tobacco?
6. Give draft of acceptable regulations of schools as to contagious diseases.
7. At a moderate temperature what is the most satisfactory relative humidity for comfort?
8. At 80 degrees F. what humidity is uncomfortable?
9. Give hygienic care of infants as to clothing, bath, and their various organs.
10. Name six diseases subject to quarantine, and how long would you quarantine each?

MEDICAL JURISPRUDENCE.

1. In what condition would you expect to find the lungs, kidneys and heart after death from asphyxia?
2. What is the difference in the appearance of burns produced before death and those made after death?
3. When a physician takes charge of a case gratuitously, is he exempt from the charge of malpractice if it can be proven that his treatment was improper, or that he neglected his patient?
4. What causes rigor mortis?
5. In women what is the last of the internal organs to putrify?
6. What is the duty of the physician when it is necessary for him to take down a dying declaration?
7. In a case of suspected infanticide, describe the method of determining whether the child breathed or not.
8. What is legally meant by feticide? Is the criminality of the act any greater if performed after quickening than before?
9. State briefly the difference between idiocy and mania.
10. In death by lightning, in what condition would you expect to find the heart? In what condition the other internal organs?

ANSWERS TO STATE MEDICAL BOARD EXAMINATION QUESTIONS.

SOUTH CAROLINA STATE BOARD OF MEDICAL EXAMINERS.

Columbia, June 9, 10 and 11, 1908.

REGIONAL OR SURGICAL ANATOMY.

1. In the lymphatics of the peritoneum, those of the diaphragm are more rapid in absorption than those of the pelvis.

To stimulate, the patient should have the foot of his bed raised, so that the fluid (salt solution) may be conveyed more readily to the diaphragm, where absorption is more rapid.

To retard the too rapid absorption of pus in the abdominal cavity, the head of the bed should be raised so that drainage may be directed toward the pelvis, where absorption is slower.

2. In *paracentesis thoracis:* The puncture should be

made in the mid-axillary line, and in the fifth, sixth or seventh spaces; it should be made midway between the ribs, so as to avoid the intercostal vessels; it should be made during inspiration, as then the spaces are wider.

3. Rupture of the kidney is of less danger than rupture of the liver and the spleen, because the kidney is retroperitoneal, and therefore the pritoneal cavity is not so liable to be infected by the extravasation.

4. In *dislocation of the shoulder:* the head of the humerus is not in the glenoid cavity, and motion of the arm is considerably impaired; in *paralysis of the deltoid,* the head of the humerus is in the glenoid cavity, and the arm is freely movable.

5. The superior oblique muscle of the eye is supplied by the fourth cranial nerve (the trochlear or patheticus); in paralysis of the same *diplopia* results. The external rectus is supplied by the sixth cranial nerve (the abducens); in paralysis of the same there will result convergent strabismus and diplopia.

6. The *most common* place *of fracture of the humerus,* is at the lower extremity of the bone. *Some of the sequelæ,* are: (1) non-union; (2) "gun-stock" deformity; and (3) loss of the "carrying angle."

7. With the arm extended, and the forearm supinated, the *brachial artery* is indicated by a line drawn from the anterior axillary fold, along the inner border of the biceps, to the middle of the bend of the elbow-joint.

8. The *femoral artery* is indicated by a line drawn from the central point of a line joining the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle on the inner condyle of the femur.

The femoral artery is *best compressed* just below Poupart's ligament; and it is *best ligated* at the apex of Scarpa's triangle.

9. *In lateral lithotomy, the anatomical points to be avoided,* are: (1) The bulb of the urethra, and its artery; (2) the rectum; (3) the pudic artery; (4) complete division of the prostate gland; (5) the left ejaculatory duct.

10. *The deep epigastric artery* is internal to indirect inguinal hernia; and external to direct inguinal hernia.

PHYSIOLOGY.

1. Conditions which *hasten* the coagulation of the blood are: (1) Moderate warmth, (2) contact with foreign matter, (3) agitation, (4) the presence of calcium salts.

Conditions *retarding* the coagulation of the blood are: (1) A low temperature, (2) the addition of neutral salts in large quantities, (3) contact with oil, (4) contact with the living vessel walls, (5) when mixed with an oxalate, (6) the injection of peptones or lead extract.

The physical properties of blood: Fluid, somewhat viscid, red, specific gravity from 1055 to 1062, alkaline reaction, saltish taste, characteristic odor, variable temperature (average about 100 degrees F.).

2. The *second sound of the heart* is *caused* by the vibrations due to the closure of the semilunar valves.

It is *best heard* at the base of the heart, over the second right costal cartilage.

The events in the heart's action coincident with the second sound, are: (1) The closure of the semilunar valves; (2) the continued dilatation of the auricles; (3) the beginning of the dilatation of the ventricles; (4) the opening of the auriculoventricular valves.

3. *Warm-blooded animals* are those whose body temperature remains almost constant.

Cold-blooded animals are those whose body temperature varies with that of the surrounding medium, but which is always a little above that of the medium.

The heat of the body is *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost.

Heat is produced in the body, by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

Heat is given off from the body, by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

4. The secretion of glands is chiefly regulated by: (1) The variations in the quantity of blood which the gland receives; (2) the nerve impulses to the gland.

The mechanism of the *secretion of urine by the kidneys* is twofold: (1) By filtration, most, if not all, of the fluid is eliminated, and also inorganic salts; this depends upon blood pressure, and takes place in the glomeruli. (2) By cell activity and selection, in the cells of the convoluted tubules, the urea and principal solids are eliminated.

5. When the facial nerve is divided, paralysis of the facial muscles ensues, and "the muscles of the face being all powerless, the countenance acquires on the paralyzed side a characteristic, vacant look, from the absence of all expression; the angle of the mouth is lower, and the paralyzed half of the mouth looks longer than that on the other side; the eye has an unmeaning stare, owing to the paralysis of the orbicularis palpebrarum. All these peculiarities increase the longer the paralysis lasts, and their appearance is exaggerated when at any time the muscles of the opposite side of the face are made active in any expression, or in any of their ordinary functions. In an attempt to blow or whistle, one side of the mouth and cheeks acts properly, but the other side is motionless, or flaps loosely at the impulse of the expired air; so, in trying to suck, one side only of the mouth acts; in feeding, the lips and cheek are powerless, and, on account of paralysis of the buccinator muscle, food lodges between the cheek and gums."—(Kirkes' *Physiology.*)

CHEMISTRY.

1. *Chemical formula,* for common salt, is NaCl; for nitrate of silver, $AgNO_3$; for sulphuric acid, H_2SO_4; for nitric acid, HNO_3; for water, H_2O.

2. Blue mass contains 33 per cent. of mercury; mercurial ointment contains 50 per cent. of mercury; and citrine ointment contains 7 per cent. of mercury.

3. Gray powder is Hydrargyrum cum Creta, or mercury with chalk, and contains 38 per cent. of mercury.

5. The *positive* pole of a battery is termed the *anode;* the *negative* pole is termed the *cathode.*

PRACTICAL URANALYSIS, MICROSCOPY, TOXICOLOGY.

1. In examining *normal* urine the following points are to be considered:

The quantity voided in twenty-four hours, its general appearance, color, odor, reaction, specific gravity, quantity of solids excreted, quantity of urea, uric acid, chlorides, sulphates, phosphates.

In *abnormal* urine, in addition to the above, examination should be made for albumin, sugar, excess of indican, acetone, blood, bile, pus, casts, epithelium, parasites, pathogenic bacteria, and foreign bodies.

2. *High specific gravity* of the urine, may indicate: Diabetes mellitus, fevers, and chronic parenchymatous nephritis.

Low specific gravity of the urine, may indicate: Diabetes insipidus, chronic interstitial nethritis, contracted kidney, some nervous disorders, albuminuria, hysteria.

3. *Transitory low specific gravity* may indicate: Hysteria, or some nervous disorders, or the ingestion of an abnormal amount of fluids.

5. *A Simple Microscope.* "With this an enlarged, erect image of an object may be seen. It always consists of one or more converging lenses or lens-systems, and the object must be placed within the principal focus. The simple microscope may be held in the hand or it may be mounted."

A *Compound Microscope.* "This enables one to see an enlarged, inverted image. It always consists of two optical parts, an *objective,* to produce an enlarged, inverted, real image of the object, and an *ocular,* acting in general like a simple microscope to magnify this real image. There is also usually present a mirror, or both a mirror and some form of condenser or illuminator for lighting the object. The stand of the microscope consists of certain mechanical arrangements for holding the optical parts and for the more satisfactory use of them."—(Gage's *The Microscope.*)

6. *Oculars in common use,* are: Those having a magnification of 5, 7.5, 10, 12.5, and 15 times.

Objectives in common use, are: *Dry:* 2 inches, 1⅓ inches, ⅔-inch, ⅓-inch, 1/6-inch and ⅛-inch; (2) *Immersion:* 1/12-inch and 1/16-inch.

7. *Symptoms of poisoning by sulphate of atropine:* Dryness of the mouth and throat, thirst, drowsiness, dysphagia, face flushed, pupils much dilated, eyes prominent, numbness and partial paralysis of the extremities, and there may be delirium and coma.

Antidotes: Pilocarpine and morphine are *physiological* antidotes.

8. *Opium poisoning: Symptoms:* In opium poisoning there may be three stages: (1) a period of excitement, in which the patient is active, talkative, and has hallucinations; (2) a period of drowsiness, in which the patient is sleepy, but may be aroused; his face is pale, lips livid, pupils contracted; this passes into (3) the stage of coma, from which the patient cannot be aroused; reflexes are abolished, pupils are contracted, the pulse is slow and irregular, and respirations are infrequent and shallow.

Treatment consists in washing out the stomach, preferably with a dilute solution of potassium permanganate; ambulatory treatment, to keep the patient awake; artificial respiration is indicated, and strong coffee should be administered by the mouth or rectum; the bladder should be emptied by the catheter.

There is no antidote.

9. *Carbolic acid poisoning* may be detected by the white and corrugated mucous membrane of the mouth; the dark or smoky urine; the brown spots wherever the carbolic acid came in contact with the skin; the odor of phenol.

Poisoning by potassium hydrate may be detected by the: sloughing of the mucous membrane of mouth and esophagus; the stomach contents are alkaline, soapy and frothy; on warming the stomach contents there is no odor of ammonia.

10. When arsenic is heated in air, it is converted into arsenic trioxide.

MATERIA MEDICA.

1. Fluid Extract of Ergot. *Dose:* ℥. xxx.

Physiological effect: It stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative, it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

2. Sulphate of Sparteine. *Dose:* gr. 1/5.

Physiological effect: It increases the force of the heart, paralyses the respiratory and motor centers, and increases the flow of urine.

3. Veratrum Viride. *Dose:* gr. ij.

Physiological effect: It reduces body temperature, reduces arterial pressure, is a respiratory depressant, relaxes voluntary and cardiac muscle, causes gastrointestinal irritation and diaphoresis.

4. Chloral Hydrate. *Dose:* gr. xv.

Physiological effect: It is a hypnotic and antiseptic, it is a cardiac respiratory depressant, and it lowers the blood pressure and body temperature.

5. Tincture of Digitalis. *Dose:* ℥. xv.

Physiological effect: It is a gastrointestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels and causes a rise in blood pressure, it also acts as a diuretic.

BACTERIOLOGY AND PATHOLOGY.

1. *Aërotic bacteria* are such as require the *presence* of oxygen as an essential to their growth.

Anaërobic bacteria are such as require the *absence* of oxygen as an essential to their growth.

2. *Three most important culture media:* Bouillon, gelatin, and agar-agar.

3. In *catarrhal appendicitis:* The musoca will be found swollen and eroded, granulation tissue may be found; the muscularis is thickened and edematous; the serosa is congested and edematous but not extensively; the contents are more or less mucopurulent and are retained in the appendix.

4. The typhoid bacilli find their way to the gall bladder, and there cause a catarrhal inflammation which modifies the chemical composition of the bile and brings about first an excessive secretion and then a precipitation of cholesterin and salts. These latter, with the bacilli and epithelial débris tend to cause gall-stone formation.

5. In *fatty degeneration* the fat is formed by changes in the protoplasm of the cells; while in fatty infiltration the fat is brought by the blood to the cells, and is there deposited.

PRACTICE OF MEDICINE AND DISEASES OF CHILDREN.

2. (*a*) *Cardiac arrhythmia* has no particular clinical significance, unless it accompanies some disease. According to Butler *(Diagnostics of Internal Medicine)*, search should be made for one or more of the following: (1) Valvular cardiac disease, especially mitral lesions, in which it is usually, but not always, a sign of beginning failure of compensation, passing in many instances into delirium cordis; simple dilatation, chronic myocarditis, sclerosis of the coronary arteries, and fatty degeneration; possibly obscure changes in the cardiac ganglia, and overstrain or impaired nutrition in wasting diseases or long-continued fevers. (2) Poisons circulating in the blood, such as alcohol, coffee, tea, tobacco, digitalis, aconite, and belladonna, or the toxins of the infectious diseases, especially of typhoid fever and pneumonia. (3) Diseases of the intracranial contents, meningitis, hemorrhage, abscess, softening, concussion, and not infrequently mental excitement. (4) Neurasthenic conditions resulting from excesses or overstrain. Brief attacks of moderate arrhythmia are not uncommon in neurotic individuals, following even a slight departure from their usual habits in food, drink, or exertion. (5) Digestive disturbances, acute or chronic, and jaundice or constipation, particularly if associated with an unusually hypochondriacal frame of mind. (6) More rarely arthritis deformans, exophthalmic goiter, and renal disease.

(*b*) *The symptoms of true angina pectoris* are: Excruciating pain radiating from the heart to the neck, shoulder and arm (generally the left); a sense of impending death; cardiac constriction; the face is anxious and pale; cold perspiration and sometimes dyspnea.

The *treatment:* Inhalation of 3 to 5 minims of amyl nitrite; spirit of nitrous ether, or morphine (gr. ¼ hypodermatically), or inhalation of chloroform may be given; heat may be applied over the region of the heart, and stimulants should be given after the attack. During the intervals severe mental or muscular exercise must be avoided.

3. (*a*) *The possible sequelæ of pneumonia,* are: Chronic pneumonia, gangrene of the lung, phthisis, empyema, nephritis.

(*b*) *Incipient pulmonary tuberculosis may be suspected from:* (1) *Physical signs:* Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

4. *The causes of anemia,* are as follows: (1) *Of the primary anemias:* The cause is unknown, probably it is some form of intoxication. Predisposing causes are: Insufficient and improper food; nervous disturbances, such as violent shock; pregnancy and lactation; gastrointestinal diseases, such as atrophy of the stomach and interstitial gastritis; parasitic diseases, such as ankylostomiasis and bothriocephaliasis; frequently repeated hemorrhages; general diseases, infectious diseases, and intoxications. (2) *Of the secondary anemias:* Bad hygienic surroundings, as insufficient food or food of bad character, inspiration of noxious gases, overwork and crowding; parasitic diseases; exhausting diseases, as cardiac, renal, or gastrointestinal diseases, cirrhosis of the liver, rickets, scurvy; chronic infectious diseases, as tuberculosis, syphilis, leprosy, malaria; frequently repeated small losses of blood; overlactation and gestation; toxemia, as Saturnism, mercurialism, and jaundice.—(From Macfarland's *Pathology.*)

7. The diagnosis is gastric ulcer with perforation.—(From Cabot's *Case Teaching in Medicine,* from which the question is taken.)

10. *Causes of Convulsions in children,* are: Overeating, especially of indigestible food; rachitis, debility from exhausting diarrheal diseases; high fever, especially at the onset of the acute specific infections; very seldom dentition, phimosis, and acute middle-ear inflammation; injuries to the brain at birth, infantile hemiplegia, meningitis, and tumor of the brain; rarely of spinal cord disease.—(From Butler's *Diagnostics of Internal Medicine.*)

Causes of vomiting in children, are: An overloaded stomach; acute gastric indigestion; acute intestinal obstruction; the onset of the acute infectious diseases, as scarlet fever, malaria, pneumonia; toxemia, peritonitis; acute meningitis; cerebral tumor.

OBSTETRICS AND DISEASES OF WOMEN.

1. *Conditions with which pregnancy may be confounded,* are: Retained menses, ovarian tumors or cysts, uterine fibroids, ascites, obesity, hematometra, physometra, hydrometra, tympanites, subinvolution of uterus, retroversion of uterus, pseudocyesis.

4. Eclampsia. The *symptoms* are: "Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc., soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonus, etc. The fit lasts fifteen or

twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions."—King's *Manual of Obstetrics.)*

Preventive Treatment: (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ.

7. Conditions warranting the induction of premature labor: (1) Certain pelvic deformities, (2) placenta prævia, (3) pernicious anemia, (4) toxemia of pregnancy, (5) habitual death of the fetus toward the end of pregnancy, (6) hydatidiform mole, (7) habitually large fetal head.

8. Twin pregnancy may be diagnosed by the following signs: (1) The abdomen may be irregular in shape and may show a sulcus indicating the space between the two fetal sacs; (2) persistent and increased tension of the uterine walls; (3) two fetal heart sounds may be heard; (4) multiplicity of small parts; (5) two fetal heads or backs may be palpated; (6) diminished fetal mobility. Sometimes it is difficult to diagnose the condition before the birth of one child.

SURGERY.

1 and 2. *Six important points to promote primary union of a wound:* (1) Stop the bleeding; (2) remove foreign bodies; (3) asepticize; (4) coapt the edges; (5) provide for drainage (if necessary); (6) rest the injured part.

Any interference with the above will retard, interfere with, or prevent the healing of the wound.

3. *Four notable phenomena in inflammation of a visible part:* (1) Redness; (2) swelling; (3) heat; (4) tenderness.

4. Bedsores. (1) *Causes:* Undue pressure and irritating secretions; a crease or fold in a sheet, a crumb of bread, a feather, or a bit of string on the sheet may cause them. Especially is this so when the skin is irritable from excessive perspiration, inefficient washing, or involuntary passages of urine. Bedsores are particularly common in spinal affections and in wasting diseases.

(2) *Prevention* consists in reducing the pressure, careful repeated washing, drying, and dusting with zinc oxide, and subsequent protection with lint or cotton-wool, etc. Leather-backed adhesive plaster may be applied over bony prominences, or, if seen early, collodion may be used. Frequent rubbing with alcohol may prove a preventive. When congestion appears, a water-bed or air-cushion may be used. Spirits of camphor or glycerol of tannin may be rubbed in twice daily, to harden the skin. Salt and alcohol (two drams to the pint) may also be used.

(3) *Treatment:* A solution of silver nitrate may be used when the skin is about to break, in the strength of gr. 20 to the ounce; and in solution of gr. 10, daily, when the skin breaks. The sloughs should be removed as fast as they form. Stimulation, good nourishment, and sleep are valuable in treatment.—(From Gould and Pyle's *Cyclopedia of Medicine and Surgery.)*

PRACTICAL HYGIENE, SANITARY SCIENCE, STATE MEDICINE.

4. *Infectious diseases which may be conveyed through the medium of the air:* Tuberculosis, pneumonia, diphtheria, measles, scarlet fever, whooping cough, erysipelas, influenza.

Through the medium of water: Typhoid, dysentery, cholera, yellow fever, scarlet fever, diphtheria.

Through the medium of food: Tuberculosis, diphtheria, typhoid, scarlet fever, cholera.

5. "The continued use of tobacco, by smoking or chewing it to *excess,* produces granular inflammation of the fauces and pharynx, atrophy of the retina, dyspepsia, lowered sexual power, sudden faints, nervous depression, cardiac irritability, and occasionally angina pectoris. Used by the young, it hinders the development of the higher nerve centers and impairs the nutrition of the body by interfering with processes of digestion and assimilation."—(Potter's *Materia Medica, etc.)*

MEDICAL JURISPRUDENCE.

1. *After death from asphyxia,* I would expect to find the *lungs, kidneys, and heart,* congested. Occasionally, in young persons, the lungs are anemic and emphysematous; the right side of the heart and lungs is usually gorged with dark-colored blood.

2. In *burns* produced *before death:* there is usually a blister, with a bright, red base, and containing a serous fluid, which is albuminous; occasionally, there will be no blister if there has been excessive shock; also, there will be a red line of demarcation between the injured and the uninjured parts, and this, being a vital process, is only developed during life.

In *burns* produced *after death* there is no true blister, no red base, and gas is present in place of serous fluid.

3. Taking charge of a case *gratuitously* causes no exemption from the charge of malpractice, in case of neglect or improper treatment.

4. *Rigor Mortis* is supposed to be due to the coagulation of the myosin in the muscles.

5. In women, the last of the internal organs to putrefy, is the uterus.

6. *The duty of the physician, when it is necessary for him to take down a dying declaration, is:* (1) To explain to the patient the hopelessness of the case; (2) to satisfy himself as to the patient's soundness of mind; (3) to write down the exact words of the dying person, without adding any comment or explanation of his own; (4) to read the declaration over to the dying person, and, if possible, have him sign it; (5) the statement should be perfectly voluntary.

8. By *feticide* is meant the unlawful destruction of a fetus before it is born. The criminality is the same whether done before or after quickening.

9. "Idiocy differs from other states of insanity in the fact that it is marked by a congenital defficiency of the mental faculties. There is not here a perversion or a loss of what has once been acquired, but a state in which, from defective structure of the brain, the individual has never been able to acquire any degree of intellectual power to fit him for his social position. It commences with life and continues through it."—(Taylor's *Medical Jurisprudence.)*

10. *In death by lightning:* the *heart* may be (1) unaltered, or (2) congested, or (3) full of blood, or (4) empty. The other internal organs are congested.

Why Mercurial Treatment in Tabetics Aggravates the Condition of Some, Ameliorates that of Others, and Is of Indifferent Use in Most Cases.—Maurice Faure, in a paper read before the ninth French Medical Congress, says that the diversity of opinion with reference to the use of mercury in tabetics comes from the diversity of results obtained. It is not possible to judge from a mass of patients without arriving at opposite conclusions. It is necessary to classify all tabetics into three categories with reference to mercurial treatment. 1. Mercurial treatment is badly borne and may cause aggravation of symptoms in cases in which the patient is the victim of accompanying intoxications (vesical infections, digestive troubles, respiratory troubles, hepatic or renal alterations, tuberculosis, cachexia, etc.). 2. Mercurial treatment is useful in tabetics, who have nervous symptoms of long standing (there being no other contraindications present), but that are still progressive. When there are only transitory troubles they disappear not to return (diplopia, pains, lack of general nutrition, slight instability, anesthesia, hyperesthesia, dysesthesia, etc.). In patients not treated by mercury such improvement is less frequent and less sure, and the prognosis for the future of the disease is generally more serious. 3. Mercurial treatment is useless (and generally indifferent) in tabetics whose symptoms have been fixed for a long time and show neither regression nor progression. To best appreciate the action of mercurial treatment we must determine for each subject the salt most useful, the dose best borne, and the best intervals for administration, since the individual tolerance varies and the results observed with the same technique are too variable to furnish reliable information. In conclusion, it is inexact to consider the mercurial treatment as the only therapeutics for tabes; it is not less inexact to consider mercury as having no place in the treatment of this disease.

Reputed Cure for the Opium Habit.—A new remedy for the opium habit is claiming the attention of the profession. The plant yielding it is the *Combretum sundaicum*, a woody climbing plant abundant on the plains in certain parts of Asia. The method of preparation and administration which appears to be invariably adopted is as follows: The branches and leaves are the parts of the plant used. The latter are separated from the woody portions, which are cut into thin slices and short lengths. Leaves and stem are roasted separately on an iron plate over a charcoal fire and then mixed together, the reason for separating being that the leaves would be charred by the amount of heating necessary for the wood. A decoction is then prepared by boiling from 8 to 11 ounces of the roasted drug in 4 gallons of water for three hours in a loosely-covered vessel and straining, at first roughly and then through a white cloth. Each patient is supplied with two bottles of the decoction, usually holding about 25 ounces each; into one he puts a quantity of burnt opium equal to the amount of his usual daily allowance, and none into the other. A dose of about 1½ ounces is taken from the first bottle as many times a day as the patient has been in the habit of smoking, usually three or four times. Each time a dose is taken the bottle is filled up from the second until the latter is emptied, when the patient continues taking the mixture that remains, without further alteration of its composition. Thus the patient begins with a dose of opium of only about one-sixteenth, or a daily dose of from one-sixth to one-fourth of his usual daily amount, and instead of smoking it he takes an aqueous extract of the residue left after roasting it in the same way as for smoking; with each dose he takes a quantity of the decoction of combretum, and the amount of extract of opium progressively diminishes to the seventeenth dose, when it is approximately only one-third of that in the first dose; it then remains constant to the last, or thirty-second dose. It is stated that in the majority of cases the cure is then effected; if it is not complete, the patient obtains a second supply of the medicine, into which is put only half the amount of burnt opium that was added to the first. As, however, the dose has been already reduced to one-third, it appears an irrational proceeding to increase it again to a half prior to a further reduction. In some cases a third bottle is necessary. When once the point is reached at which the patient can do without opium, further use of the combretum is not considered to be necessary; the "cure" is thus not a mere substitution of one drug habit for another.—*British Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the two weeks ending December 18 and 25, 1908:

PULMONARY EMBOLISM FOLLOWING OPERATION.*

BY C. L. GIBSON, M.D.,

NEW YORK.

ATTENDING SURGEON, ST. LUKE'S HOSPITAL.

WE have had in St. Luke's Hospital since 1899 fifteen cases of sudden death following operation which have been attributed to pulmonary embolism. Such autopsies as have been performed have verified the condition. The five cases here related were in my service.

CASE I. Kate P., forty-two years. Somewhat anemic from prolonged uterine hemorrhage. Small submucous fibroid. Enucleation of fibroid by vaginal route. Death on the eighth day, fifteen minutes after sudden onset of symptoms.

Autopsy: Local condition perfect; no thrombosis of pelvic veins. Two clots in right branch of pulmonary artery.

CASE II. Charlotte H., twenty-six years old. Strong, healthy woman. Chronic appendicitis. Operation extremely simple—intermuscular incision, inversion of appendix stump. Perfect convalescence. Upon the ninth day she had just gotten out of bed and was sitting in a chair as I made my rounds. I thought she looked tired and somewhat different from her previous satisfactory condition. There was a slight rise in temperature and I recommended that she go back to bed. Five minutes later she developed sudden oppression and cyanosis and was dead within ten minutes. Autopsy: Wound conditions and venous trunks negative. Clot in main pulmonary artery and the right branch. There is a note of several slight patches of atheroma, particularly of the mitral valve—a probably significant feature in a subject of twenty-six years.

CASE III. Mary J., thirty-eight years old. Well defined abscess. Appendectomy and drainage. Death on the tenth day, thirty-five minutes after onset of symptoms.

CASE IV. Inez H., thirty-five years old. Strong colored woman. Perirectal abscess. Incision and drainage. Death on the fourteenth day, after an uneventful course, ten minutes after the initial symptom.

CASE V. Albert B., forty-two years old. Chronic appendical abscess of long standing. Complex condition requiring resection of cecal wall. Perfect convalescence. He was found dead in bed on the tenth day, having been in the best of condition fifteen or twenty minutes previously. Autopsy: abdominal findings negative. Clot in the left branch of the pulmonary artery.

The experiences just noted can be duplicated in most institutions where many operations are performed. Also I cannot think of a single surgeon of considerable experience with whom I have conferred who has not had similarly disturbing occurrences.

The condition has long been recognized, and lately a good deal of attention has been given to it all over the world. Theoretical explanations are numerous and efforts at prophylaxis are being made and even attempts at cure by operative interference.

The mechanical transmission of clots formed in the venous system toward its terminus, the pulmonary artery, is readily comprehensible. It is also easy to understand how under certain conditions such clots are formed or their development favored, namely, in deficiencies of the circulation, essential blood changes, as a result of extensive or long standing diseases or inflammations, and severe trauma, particularly from certain surgical procedures or manipulations. Given such conditions, we must more or less resign ourselves occasionally to this casualty of pulmonary embolism. Coming as a sequel of an operation which has been gently and properly performed without undue malhandling of the tissues, the unsatisfactory termination can in all fairness be attributed to the condition rather than to the procedure.

The purpose of this paper is to call attention to the necessity of inquiry into the causes of pulmonary embolism in quite a different class of cases—that is, following operations often of a quite benign character, properly performed on subjects whose physical condition makes them an apparently good risk for operations such as the radical cure of uncomplicated herniæ, particularly the inguinal variety, "interval" removal of the appendix, and many operations on the female pelvic viscera.

Nothing can be more disheartening after an operation performed *secundum artem* on a patient of vigorous health and physique, followed by perfect convalescence and ideal wound healing, when suddenly, out of a clear sky, death comes within a few minutes after the first symptom which we clearly recognize as blocking of the pulmonary circulation. Even in these cases it might be a melancholy satisfaction, a sort of moral whitewashing, if we could demonstrate the occurrence in the field of operation of signs of nature's overefforts of repair in a more or less extensive thrombosis of the venous circulation. Autopsies in this particular class of cases are, however, provokingly free from evidences of mechanical phenomena, and generally leave us as ignorant as ever, much less furnish any hint how to apply the benefits of experience to our further practice.

The absence of a demonstrable mechanical sequence gives a certain support to those who refer the formation of the original clot to the right heart with extension or transmission to the pulmonary ar-

*Read before the Surgical Section of the New York Academy of Medicine, December 4, 1908.

tery, or even developing primarily in that vessel. While such an explanation sounds attractive in certain cases, it fails to appeal to me when it is sought to apply it to the particular class of cases we are considering—persons in good health free from circulatory lesions. It is ridiculous to say that such people can get up a stagnation of the circulation merely from a few days' confinement to bed. This theory is, however, the popular one and its lack of value will be duly considered.

No end of views have been advanced—some of them quite fanciful, while others seem reasonable in the class of cases first mentioned, but none will satisfactorily cover those we are more particularly interested in.

In a very few instances there is an explanation in the presence of phlebitis or thrombosis of some portion of the venous system at a distance from the operative field, such as the deep pelvic veins or the femoral vein, usually the left. This condition simply changes the form of the inquiry to—why the phlebitis? Why phlebitis of the left femoral vein follows an "interval" appendectomy has, of course, been widely discussed. None of the manifold explanations holds water, and it does not lie in the scope of this paper to discuss this phase, which seldom enters into the conditions we are interested in.

In seeking for light on our subject we turn naturally to some of the elementary conditions, such as age, sex, kind of operation, wound healing, etc. Some of the observations here recorded are derived from tabulating a hundred and odd cases obtained from various sources, but the dissimilarity of the conditions forbids any attempt to formulate them except tentatively.

The sex—there does not seem to be any preponderance. Lotheissen, however, finds it much more frequent in men. The age is of some significance, for only about fifteen per cent. are recorded as under forty, while a considerable majority come between forty and sixty. None was noted before twelve or over eighty. It is interesting to note of the cases which were described as pulmonary embolism of an accute and dangerous type, but recovering; the subjects were practically all quite young.

Anesthesia, or the kind of anesthesia throws no light, death following all forms, including local and spinal. Suppuration, though possibly a factor, as one can readily understand, is not necessarily so, as many autopsies showed absolutely irreproachable conditions.

Naturally vascular changes and distinct blood alterations, if present, might be blamed. Likewise hemorrhage antecedent or occurring during or after operation. Milk diet even has been under suspicion and it has been proposed to decaleify it by the use of citric acid.

A factor that stands out most prominently is the location of the operative field, practically always below the belt—laparotomies, hermotomies, or operations on the extremities.

Finally we come to the most prominent feature—the influences of confinement in bed in promoting coagulation and the formation of clots. As showing the diversity of opinions on this particular point and of the etiology in general, the following notes are appended, being taken from the discussion of Trendelenburg's, Kümmell's and others' papers on this subject at the German Surgical Congress of 1908:

Rehn of Frankfort does not favor getting patients out of bed so early. Pulmonary aeration may be a protection against marasmus thrombi, but not against the septic.

Lauenstein of Hamburg says postoperative emboli are due to sepsis.

Abel of Berlin holds that in gynecological practice nothing is to be gained by getting patients out of bed early unless in the case of elderly individuals.

Meinert of Dresden thinks the majority of postoperative emboli are due to concentration of the blood from loss of water during the operation. Consequently a generous supply of water even during the operation is indicated.

Olshausen of Berlin says that in embolism after laparotomy, myomectomy stands the highest, perhaps the elevated pelvis, the patient hanging down on her flexed knees, is to blame. Shoulder supports should be used to counteract this fault.

Muller of Rostock says that following fatal embolism dilatation of the saphenous vein is often observed at the autopsy, which may have favored the formation of a thrombus.

Gebele holds that the chief prophylactic factor of pulmonary embolism is asepsis. Cardiac stimulation and pulmonary gymnastics are important. After laparotomy he would keep the patient fourteen days in bed, and getting up earlier may be the cause of embolism.

Henle of Dortmund, influenced by the bad results of getting patients up early in the Breslau Clinic, keeps his patients fourteen days in bed. The lower extremities are massaged to prevent thrombus formation in the saphenous vein.

Hochenegg of Vienna thinks the most important factor is infection from the intestinal canal; early purgation is recommended.

Körte keeps laparotomy patients fourteen days in bed to get a sufficiently firm union; getting up earlier is dangerous, as plugs in ligated vessels may be dislodged.

Krönlein of Zurich says that in view of the greater frequency of emboli in gynecological practice research regarding a peculiar condition of the pelvic veins in the female should be made.

Heller of Quedlinberg believes that patients with incisions above the umbilicus should get up early, as they have greater difficulty in breathing in the prone position.

Löbkin of Bochum says that circulatory conditions should be considered and the urinary output watched; subcutaneous infusions may be judiciously employed.

Eiselsberg of Vienna keeps laparotomy patients in bed two weeks, a shorter period is distasteful to them.

The most popular single theory of to-day makes immobility and confinement to bed play an important part in the formation of venous thrombosis. As has been already stated, while we may admit its possibilty in elderly people, those with cardiovascular and chronic pulmonary lesions, the cachectic and the subjects of dyserasias—again I repeat, it is ridiculous to say that such is the course of events in healthy and relatively young subjects as a result of putting them to bed for a few days. As a matter of fact, and I wish particularly to emphasize this most important point, *the majority of cases of embolism occur early after operation.* I have grouped my collection of cases into three classes: First week, second week, and all later cases up to three months; and we get these signifi-

cant results—a steadily declining proportion of emboli: First week after operation, 60 per cent.; second week after operation, 29 per cent.; all others up to three months, 16 per cent. Moreover, there were more deaths in the first and second twenty-four hours after operation than on any other days. Some of the patients, it might be noted, had been up and about for days, even weeks, when the fatal accident occurred.

Similar observations are recorded, *e. g.* Ranzi of Eiselberg's clinic reports: First five days, 23 cases; second five days, 9 cases; third five days, 8 cases; fifteenth day to three months, 7 cases. If the above data shall be found to be consistent such findings must obviously agree against the growing tendency to rush patients out of bed; some operators let patients go about the day following a laparotomy.

If so many cases of embolism occur early it is obvious that phlebitis, particularly of the femoral vein, cannot often be a factor, as phlebitis comes at a later period.

Having taken up the main points of interest, what do we find? Practically only three factors stand out prominently.

First. The age of the patients—young individuals are more or less exempt, and if affected may perhaps recover presumably on account of the yielding elasticity of their vessels which may allow the blood to push its way beside a clot. The age from forty to sixty being most afflicted, we are probably dealing with conditions of vascular changes over which the operator has little or no control. He should, however, be more on the alert to recognize or anticipate such changes, and their existence should be considered in operations which are a matter of expediency rather than actual necessity.

Secondly. That practically all those cases of embolism follow interventions below the diaphragm and even lower "below the belt." Therefore we must study the local conditions more closely for further light.

Thirdly. That at the present time there is little or no justification in rushing patients out of bed as a routine measure, it being granted that in individual cases and conditions a preexistent or suspected tendency to stagnation or coagulation should be counteracted by this and other measures.

I may say that I have felt that this encouragement of a strenuous convalescence has sometimes originated in a desire for a speedier rotation of cases in overcrowded wards.

What, then, shall we do to prevent pulmonary embolism in the seemingly preventable cases? I think the matter must still be left open; but I feel very strongly that we ought to make it a subject for constant study, and the main object of this paper was to center attention on it. Personally I intend to continue this preliminary work, hoping that eventually data of a convincing character may be obtained for our guidance. I take the liberty hereby to invite my surgical colleagues to favor me with details of such cases which, if they attain a sufficient number, may lead to valuable information. For data so obtained must be much more reliable than indiscriminate statistical compilations.

As Dr. Willy Meyer will tell us this evening about the attempts of Trendelenburg to remove the clot from the pulmonary artery, the subject can be omitted from this paper. While according a full measure of admiration for the conception of this procedure it seems doubtful if it ever can be of great value and that, for the occasional success which may result, other individuals who might possibly have overcome the condition might find in the severity of this operation their *coup de grace*.

The operation is described in several of the literature references:

A CASE OF ADDISON'S DISEASE, WITH AUTOPSY.*

By CHARLES H LEWIS, M.D.,
NEW YORK.
VISITING PHYSICIAN TO ST. VINCENT'S AND COLUMBUS HOSPITALS.

ALTHOUGH the clinical picture of the disease accurately described by Thomas Addison in 1855 and called by his name has undergone little change and no improvement, the pathological lesions underlying the picture are still undetermined and no more clearly defined than in his day.

Whether Addison's disease is due to organic or functional changes in the adrenals, in the sympathetic nervous system, to a combination of both, or to neither, but to some other unknown cause, is still dark ground in pathology, and cases have been reported exhibiting the clear-cut clinical picture of Addison's, with post-mortem findings, which might be classed under any one of the foregoing etiological heads. The spirit of agnosticism pervading an exhaustive article in "Ziemssen's Cyclopedia" by Merkel, in 1875, runs with equal or greater prominence through Reis's excellent résumé on the subject in 1907—a generation later.

A weak heart and pulse, discolorations of the skin and mucous surfaces, great muscular debility, gastric and intestinal irritation, and anemia appear in the clinical picture with constancy and strength, while the post-mortem findings of the reported cases reveal themselves in discouraging variety. Addison, himself, after the publication of his original article, on further study of the disease, switched from the adrenals to the sympathetic nervous system as the organic structure necessarily implicated.

The rarity of the disease and the scarce and scattered autopsy records are no doubt largely responsible for the lack of harmony between individual reports, and the resulting difficulty of drawing safe conclusions as to the true pathology of the disease. Osler has personally observed but seventeen cases. The records of St. Vincent's Hospital for the last seven years contain but two cases. The records of the New York City Board of Health show, in 1906, out of 76,203 deaths, but six from Addison's disease, and in 1907 but thirteen out of a total death

*Read at a meeting of the Section on Medicine of the New York Academy of Medicine, December 15, 1908.

record of 79,205. As Addison's disease is invariably fatal after an average course of two to three years, the number of deaths in two consecutive years would be a fair estimate of the number of cases. Of course, the number of autopsies is much less. Upon these grounds the following case, with autopsy, seems entitled to record:

Domenico F., Italian, entered St. Vincent's Hospital, January 15, 1907. His estimated age was 54 years. His occupation a hatter. He spoke no English and but little intelligible Italian. Had no friends, and the only history elicited was extracted from him after repeated questionings in all kinds of Italian. His reluctance to answer questions seemed partly due to his lack of understanding, but mainly to a desire to be let alone. He answered affirmatively or negatively, apparently according to which word came first and easiest and with no manifest interest or regard to the facts of his case. Under such circumstances the history was incomplete and unreliable.

When roused his mind was rational, and he impressed one as being not stupid but pertinaciously indisposed to make the slightest exertion of voice, nod of the head, or even wink of the eye. His very facial expression was a literal translation of "that tired feeling." His face, hands, and arms were rather deeply bronzed, of uniform hue, but not exceptionally dark for a native of Southern Italy. No other bronzed patches were present on the body, nor were pigmented spots seen on the skin or mucous surfaces. He denied pain and gave no evidence of local tenderness. The radial pulse was almost imperceptible. Taken from the brachial it was comparatively slow (84), extremely low tension but regular in force and frequency. There was no demonstrable thickening of the arterial wall, which had a soft and almost flabby feel.

Solid food he absolutely and strenuously (for him) refused, taking liquids sparingly and under persuasion. Whether this was due to the extra muscular exertion of mastication or swallowing, or to some prior ill effects of food on the stomach and the fear of a repetition of the disagreeable experiences, was unknown; but his constant and sole response of "non potet" (not able) when urged to take food, inclined us to the latter opinion. He was fairly well nourished. No abnormal nervous symptoms, objective or subjective, could be made out. His general appearance suggested a rather grave anemia, but the blood examination recorded later did not carry out the suggestion.

The meager history which was obtained embraced an illness of three weeks before admission, the dominant symptoms of which seemed to be a general and progressive weakness and a failing appetite. He admitted some vomiting and transient pains over the epigastrium. Little information could be gathered and nothing of importance about his family or personal history prior to this present illness. A careful examination revealed in addition to what has been stated a dull and apathetic expression, eyes slightly icteric, mouth, tongue, and teeth foul and coated, and an expired breath with an odor resembling that of putrid fish. No pigmented spots were to be seen on any mucous surface.

The heart's apex beat was made out with difficulty in the normal area. The sounds were weak. No murmur could be detected. The right lung was congested at the base, otherwise normal. The left lung presented some rales with dullness and signs of slight consolidation at the apex, also a congested area at the base. The spleen was hard and easily felt below the border of the ribs. Pulse 84. Temperature 99.4°. Respiration 18.

The next day, January 16, urine, quantity 21 oz. in 12 hours. Has trace of albumen and considerable indican. Few hyaline and granular casts, otherwise normal.

Blood.—White corpuscles, 12,000; erythrocytes, 3,900,000; hemoglobin, 80 per cent. Differential count; Polynuclear leucocytes, 73 per cent.; mononuclear, 4 per cent.; lymphocytes, 22 per cent.; eosinophile, 1 per cent.; basophile, 0 per cent.

In the six succeeding days no new symptoms appeared, but those already mentioned became more and more pronounced, particularly the failing heart, the mental apathy, and the physical weakness. Vomiting occurred a few times. The temperature ranged from 98° to 99.6°, and the pulse, while constantly fainter, never went above 98, nor so far as ascertained did it lose its uniformity in force or frequency. Stimulants in generous doses had not the slightest influence on its action. Adrenalin was given by the nedle, but with no appreciable effect.

The patient died January 22, seven days after admission.

Autopsy at St. Vincent's Hospital, January 27, 1907, by Dr. G. R. Satterlee, to whom I am indebted for the following notes:

Body is that of a well-developed male. The panniculus adiposus is well marked, but the skin shows some wrinkling caused by loss of flesh. The skin shows slight bronzing, particularly over the face; no patches of pigmentation are present.

Chest and lungs.—The left lung is bound down to the pleura by very extensive old adhesions. There are a few old healed tubercles at the apex and marked congestion at the base of the left lung. There is a moderate amount of interstitial fibrosis. Over the right lung there are a few old adhesions, especially at the right apex. There is a moderate degree of interstitial fibrosis and congestion at the base.

Heart and vessels.—The aortic arch shows a few fatty patches of atheroma. The right auriculoventricular orifice admits four plus fingers. The valves show patches of thickened intima but no actual ulcers. The walls of the right heart are extremely thin: the cavity contains a moderate amount of antemortem clot. The left auriculoventricular opening admits one and a half fingers; the valve shows a slight thickening. The walls of the left heart are very flabby; the muscle is very pale and fatty. The aortic valves are normal. The coronary arteries are apparently normal.

The spleen is enlarged to about one and a half times its normal size. The organ is bound down and firmly attached to the omentum by old adhesions. There is a marked amount of perisplenitis; the tissue is very firm, pale and shows a moderate amount of interstitial splenitis.

Kidneys.—The left kidneys is normal in size; the surface is smooth; the capsule non-adherent. The cortex is thin and shows a moderate amount of fatty change. The capsule of the right kidney is moderately adherent; the cortex and rest of the kidney is the same as that on the other side.

Adrenals.—Both adrenals are occupied by large irregular firm white tumors, nodular in character, and about 7 cm. long by 3 x 2 cm. in thickness. Cut surface shows small necrotic and apparently hemorrhagic areas. There does not seem to be any normal adrenal tissue left.

The ureters and bladder are normal. The prostate is normal except for a slight fibrosis.

The liver is small, the tissue firm and shows a considerable amount of perihepatitis. There are two small calcareous nodules about the size of peas underneath the capsule. The cut surface of the liver shows irregular patches of fatty infiltration. No secondary deposits of any kind can be seen.

The gall-bladder contains about 30 c. c. of dark green bile. The gall duct is patent.

The stomach is dilated, the muscular wall is thin, the rugæ are absent, and there is a small ecchymotic spot in the mucosa.

The small intestine shows a few ecchymotic patches about 12 inches from the duodenojejunal junction. The retroperitoneal lymph nodes in the region of the jejunum are considerably enlarged, hard and massed together, forming by their pressure a partial stricture of the gut. The sympathetic ganglia are surrounded by masses of these enlarged glands. Section of these glands shows them to be white fibrous in character. The abdominal aorta is normal, except for two small fatty plaques.

Cause of death.—New growths in both adrenals (tuberculosis). Fatty degeneration of the heart, liver, and kidneys, the disease commonly caused by these conditions being Addison's disease.

Microscopical Examination: Heart.—Section of the wall of the left ventricle. The heart cells stain faintly with eosin and show considerable vacuolization of their cytoplasm; the striations are faintly marked and there is a moderate amount of hematogenous pigment. There is no increase of the interstitial tissue. The blood vessels are normal. The endocardium is normal. Frozen sections stained with Scharlach show fatty vacuolization of the cardiac cells.

Liver.—The liver cells show fairly well marked vacuolization and fatty degeneration of their cytoplasm and the nuclei are faintly stained. There is no increase of the intracellular or periportal connective tissue. There is, however, a considerable infiltration of the capsule of Glisson with lymphocytes, and to a certain extent in the intralobular capillaries. The bile ducts in places show a moderate amount of proliferation. The blood vessels are normal. Section of a calcareous nodule on the surface of the liver shows it to be outside of the liver parenchyma in the external capsule, and around it a slight amount of perihepatitis.

Spleen.—Aside from a moderate amount of congestion of the blood vessels, the organ appears normal. There is a moderate amount of hematogenous pigment. The blood vessels are normal. The same can be said of the accessory spleen.

The abdominal aorta shows one large fatty degenerated area, involving the intima and about one-half the media.

Pancreas.—There is a marked degeneration of the epithelium of the acini, which is probably fatty in character. There is no abnormality of the interstitial tissues, ducts, blood vessels, nor of the islands of Langerhans.

Kidneys.—The epithelia of the convoluted tubules are very markedly degenerated and broken down, and in some places show destruction of both cytoplasm and nucleus. Stained with Scharlach and saffranin, the cytoplasm of the cells shows very marked fatty degeneration. The glomeruli are somewhat swollen; the cells of the capsule of Bowman show some fatty degeneration. The epithelia lining the collecting and straight tubules show also fatty changes. The capsule of Bowman is somewhat thickened and shows hyalin degeneration. Both large and small blood vessels are much congested, the walls of the larger ones showing slight hyalin degeneration. There is no increase in the interstitial connective tissue. There is a small collection of lymphocytes near one of the veins.

Renal artery shows a slight hyaline degeneration. The lymph nodes, mesenteric, and retroperitoneal show marked hyperplasia but no necrosis. The thyroid gland; normal. The large intestine; normal.

Sections of the tumor of the right adrenal.—The tumor consists almost entirely of a round-celled infiltration without the formation of distinct tubercles. Scattered throughout are areas of coagulation necrosis, on the edges of which are numerous large typical giant cells with multiple nuclei, situated peripherally, as many as fifty or more, deeply staining but often fragmented. The cells in the remainder of the tissue are chiefly lymphocytes with some polynuclear and plasma cells, and a few scattered epithelia, probably remnants of the epithelia belonging to the parenchyma of the adrenal body.

The right adrenal shows similar conditions, but modified by post-mortem changes.

Diagnosis.—Tuberculous inflammation of both adrenal bodies.

The sympathetic ganglia.—Many of the ganglia cells contain an excessive amount of brown pigment. All the ganglia cells show a fair amount of chromatolysis.

Pathological Diagnosis.—Tuberculous inflammation of the adrenal bodies, fatty degeneration of the heart and liver, chronic parenchymatous, and glomerular nephritis with fatty degeneration of the kidney cells, fatty degeneration of the pancreas, hyalin degeneration of the blood vessels, dissemination of the tubercular process into the retroperitoneal and mesenteric lymph nodes, and possibly commencing in the liver and kidneys. Degeneration of the ganglia cells of the sympathetic ganglia.

This case seems to come under that class of Addison's in which both the suprarenal capsules and the sympathetic system are affected, the former by tuberculosis, the latter through pressure on its large ganglia by the adjoining enlarged lymph nodes, causing degeneration of the ganglia cells. This is the pathology of the disease at present accepted by L. Reiss of Berlin.

51 West Fifty-eighth Street.

CONGENITAL ABNORMALITIES OF THE PENIS AND THEIR INFLUENCE UPON THE ACQUISITION AND COURSE OF GONORRHEA.*

By E. WOOD RUGGLES, A.M., M.D.,

ROCHESTER, N. Y

MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, AMERICAN ASSOCIATION OF GENITOURINARY SURGEONS, AMERICAN DERMATOLOGICAL ASSOCIATION ETC., ETC.

The penis, more than any other organ, member, or feature of the human body, is subject to the most various changes in development and in appearance. Its size may vary from less than nothing, being merely an invagination of the skin, to an enormous member of formidable dimensions. The prepuce may be altogether absent or reach a development entirely out of proportion to the size of the

*Read at the Annual meeting of the American Association of Genito-Urinary Surgeons, Hot Springs, Va., May 1 and 2, 1908

organ itself and the opening thereof may be contracted to the caliber of a fine needle, or it may even be imperforate. The meatus may be located at any point in a median line extending from the penoscrotal junction on the lower surface along the raphé and frenum to the apex of the glans and from this point along the dorsum to the pubis, while its size varies from a pin hole to a slit occupying the major portion of the glans. It may also be double or triple, or completely absent. The urethra also manifests the most amazing complexity of form and branching in various subjects.

Stranger still are the variations of development in so-called hermaphroditism, in which the outlines of the penis recede, as seen in a series of cases, losing more and more their distinctive character, until the walls of a hypospadiac urethra come to correspond to the labia majora and the rudimentary penis to a clitoris, and an almost perfect imitation of the external female genitals is produced. Certainly the penis is the most versatile member of the human anatomy in its variations from the regular type.

The first of these abnormalities which I shall consider and the most simple and frequent is the contracted meatus. The normal meatus, in an average sized penis, has a length of about three-eighths of an inch and should let pass a number 30 Fr. sound with ease. There are, however, many meatuses which are apparently contracted, *i.e.* their length is a third or more less than that above stated, which in reality are not functionally contracted, since they permit the passage of a large stream of urine without effort and admit a 30′ sound easily.

At the other extreme is the "pin-hole" meatus, sometimes not larger than a fine needle. Such a meatus has in gonorrhea a similar effect to that of an insufficient opening of an abscess. The secretion is dammed up and while the apparent discharge may be slight, there is an unusual amount of pus within the urethra and the gonococci are very much more likely to penetrate the mucous membrane deeply, to enter the urethral follicles, and to migrate to the posterior urethra and to the prostate and seminal vesicles. Of course such a case may recover promptly, but this is due to the greater resistance of the tissues, which, in my opinion, is not caused by their more perfect vitality, such as furnishes protection against infection by the tubercle bacillus in the lungs, but by their anatomical structure, the mucous membrane being less permeable and the mouths of the follicles and the ejaculatory and prostatic ducts smaller or at least less pervious for the germs than in the severer cases. That such an idiosyncrasy exists in these cases is demonstrated by the fact that patients who suffer from severe or obstinate complications or from gonorrheal rheumatism during their first attack of gonorrhea, generally are affected by the same complications at subsequent attacks. It is my custom, in a case of either acute or chronic gonorrhea, to enlarge such a meatus at once, if the individual will consent, although I have sometimes lost a patient by the suggestion.

Now as to the moderately contracted meatus. If the course of the disease is favorable, especially if it remains confined to the anterior urethra, I let it alone. In a good many cases of long standing, however, some instrumentation is necessary to a cure, in my practice at least, and a meatus which cannot be dilated above 25 Fr. will not admit an instrument large enough to be effective.

As to the relative frequency of contracted meatus I have no data, not, up to this time, having made or seen any notes upon the subject. One thing is certain, however, that circumcision in some manner causes this condition, for the majority of Hebrews present it to a greater or lesser degree.

Dr. E. S. Talbut gives statistics[1] obtained from three of the leading rabbis of Chicago. One of them who had circumcised 3,400 boys found the prepuce absent in about 3½ per cent. of the cases. Another, who had performed circumcision 10,000 times found the prepuce lacking in 500 cases, partially developed in 300 cases, slightly developed in 2,000 cases. The third had performed 4,400 circumcisions and found the prepuce absent in 15 cases, partly wanting in 200, and only slightly developed in 2,200 cases, *i.e.* over 50 per cent. of abnormal development. Absence of the prepuce does occur in other infants, but so rarely that I doubt if any one in the room has observed it.

In view of the above facts as to the hereditary transmission of an acquired mutilation, technically speaking (personally I am in favor of circumcising all infants whose prepuce covers the glans) it is evident that other parts of the male organ may also be influenced and a tendency to contracted meatus be transmitted. I formerly attributed it to injury of the meatus by cutting too near the glans, but the proportion of cases is too large to be in accord with this theory.

The contracted meatus (which, however, is often very dilatable) and, as a rule, narrowed urethra, which accompany hypospadias, are also obstacles to rapid recovery from gonorrhea, especially in cases where instrumentation becomes advisable.

A long prepuce with a narrow opening may act in the same manner as a contracted meatus in prolonging a case of gonorrhea, and I have seen a few such cases in which circumcision was necessary before a cure could be effected.

Another abnormality of the urethra which occasionally affects the prognosis of a gonorrhea is the presence of what are termed accessory or paraurethral canals. The Germans call them "paraurethrale Gänge," and the French "canaux accessoires." The earliest mention of this condition was made by Andrew Vesalius in 1543. In his work "De Humani Corporis Fabrica" he speaks of a law student who had two openings in the glans penis, one of which ejected semen and the other urine. The old surgeon Guilhelmus Fabricius Hildanus writes, in the year 1600, of a twelve year old boy whom Nature had provided with two urethræ through both of which he passed urine without difficulty. They were situated at the usual locality, one above the other and separated by a thin membrane, the lower being somewhat deflected so that the stream was directed downward. Similar cases have been occasionally reported since, but only in 1885 did Oedmansson of Stockholm call attention to their importance as regards gonorrhea. He speaks of an "urethritis externa" in which these passages are inflamed without any urethral infection. Already before this time, in the "Anatomical Nomenclature" published at Basel, there had been mentioned, as occurring in women, the "ductus paraurethrales," consisting of the openings of very narrow canals existing at the side of or posterior to the female meatus urinarius and communicating with microscopic urethral glands. These are said to be often the seats of gonorrheal infection, sometimes independently of the urethra.

Jadassohn[2] makes the first classification of these passages. His first class includes the preputial canals opening on the prepuce or at either side of the frenum, which he regards as displaced Tyson glands or crypts, *i. e.* gland-like invaginations of the epidermis. The second class includes the minute canals opening close to the meatus or on the mucous membrane just within the urethra. He considers it possible that these in reality consist only of abnormally placed openings of some of the Littré glands. The third class consists of canals on the under surface of the penis, near or crossing the raphé. He mentions a fourth group of canals upon the dorsum of the penis, but has observed no cases of this variety.

Strictly speaking, the term paraurethral canals, as Stieda[3] points out, should only be applied to the second class of cases. For the third class he suggests the term "ductus cutanei penis."

The most common form of these canals is the so-called "double urethra." The title is a misnomer, according to Le Fort,[4] who has published a report on the various fistulæ of the penis and who maintains that this double urethra is not a second urethra at all, but a pouch with a blind ending, generally a continuation of the lacuna magna to the meatus.

In spite of Le Fort's contention, however, there are in medical literature, three authentic cases of true double urethra, in which there existed two separate canals leading from the bladder to independent meatuses upon the penis, the upper canal in each case terminating in an epispadiac opening on the dorsum.

Pribram[5] reports one case. There was a moderate epispadias, the normal urethra opening upon the dorsum of the glans one-eighth of an inch behind the tip. At the border of the pubic hair, exactly in the middle line of the dorsum, was a second, funnel shaped opening, admitting a No. 28 Fr. sound, and easily dilatable to twice that size. The canal was one and two-fifths inches deep, ending apparently in a blind pouch where the two corpora cavernosa unite. The patient died later and at the autopsy it was found that a similar blind pouch emerged from the bladder above the vesical end of the urethra and almost joined the external one, the two being united by a short fibrous cord under the pubic bone where the canal had been obliterated. In this case two urethræ had evidently existed primarily, the upper one being later occluded for a certain distance.

Meissels[6] mentions a man 27 years old, who had since childhood an opening on the dorsum of the penis, two-fifths of an inch behind the glans. At ejaculation there was an outpour of fluid from both openings. Urination occurred promptly from the normal urethra, but there was a feeling as if it were trying to pass by the other also. A No. 15 Fr. sound could be passed to the distance of five inches. On injecting permanganate solution in the abnormal opening, most of it could be passed by urination through the normal urethra. No opening of this passage into the normal urethra could be found with an urethroscope.

Stockmann[7] relates an interesting case concerning the double urethra as to the existence of which there cannot be the slightest doubt. The young man, twenty-four years old, had had chronic gonorrhea for four months. On retracting the foreskin there was exposed a deep furrow, covered with mucous membrane, extending from the meatus along the dorsum of the glans and pendulous portion, nearly to the pubes. At the anterior extremity was the orifice of the normal urethra about in its usual position, but lying concealed at the bottom of the furrow. At its posterior extremity a fold of the prepuce bridged over the furrow, forming a funnel shaped opening through which a No. 10 Fr. catheter could be passed into the bladder without difficulty, and a free flow of urine followed. An 18' catheter was then passed through the normal urethra, when urine flowed freely from both catheters. On ordinary micturition the urine began to flow first from the upper opening and a few seconds later came from the normal urethra. During coitus no semen appeared at the time of the orgasm but somewhat later flowed from both orifices. On urethroscopy no opening connecting the two urethræ could be seen nor could a catheter lying in the upper urethra, but, on cystoscopy through the normal urethra, a catheter passed through the upper urethra could be seen projecting into the bladder.

The cause of all these anomalies is gone into thoroughly by Stieda, Rona, and others in studies on the development of the fetus, but it would take up too much space to enter upon the subject here.

A very few cases of triple urethra have been mentioned. Luxardo[8] describes a case of gonorrhea in which there were three openings at the site of the meatus, one of which gave exit to semen but not to urine. Of course this could not be termed a true urethra. The two lower passages appeared to communicate and both had gonorrhea.

Dr. E. B. Ward[9] reports a similar case of his own. "A young gentleman called at my office for treatment and on examination I found that the same anomaly occurred in this case (as above), *i.e.* the meatus presented three distinct openings. Nor was this anomaly confined to him but his two other brothers presented the same rare specimen of malformation."

Not infrequently we find blind canals of varying depth emptying within the urethra, at any point between the external sphincter and the meatus. Rarely or never are such canals found in the posterior urethra, as the glands of its mucous membrane are fewer and less developed. We occasionally meet a case in which the cause of the persistent or relapsing character of a gonorrhea is cleared up by the use of the urethroscope. We find a blind canal of greater or less depth, which presents pus containing gonococci at its opening, especially on being stripped by the finger from without, while the remainder of the urethra is nearly normal. If such a sinus is a quarter of an inch or more in depth it should be slit open with a narrow, probe-pointed knife, the urethroscope being inserted so that the opening of the sinus lies just beyond its distal extremity. Even after this is done the infection may persist in the portion of the canal which cannot be divided, owing to the probe point of the instrument. In such a case as well as in canals less than one-fourth inch in depth, a cure may be effected through adhesive inflammation, set up by the introduction into the sinus, by means of the urethroscope, of a fine silver or copper wire upon which lunar caustic has been fused. This is easily accomplished by holding a piece of the caustic near to an alcohol flame until it softens and then drawing the extremity of the wire through it.

In German medical literature one reads of a great many cases of relapsing gonorrhea, in which the patient, after being apparently cured, develops a reinfection, although denying any possible exposure,

and in which the gonococci are found in one of these minute pouches whether at the meatus or within the urethra. Their caliber may vary from the size of a fine cambric needle to that of a knitting-needle and larger.

These paraurethral passages also exert a certain influence upon the acquisition of gonorrhea. As is well known, intercourse with a gonorrheal woman, even when in the florid stage, is not certain to transmit the disease. I have known of numerous instances where two individuals performed coitus with the same woman in succession and only one was infected with gonorrhea. As a rule it is the first offender who becomes the victim, he seeming to absorb or mechanically remove all the discharge, but this is by no means always the case, and I had one patient who was the last of three; yet he acquired the disease while the others remained free. The two former took the precaution to urinate directly afterward, thus probably washing away whatever pus had entered the meatus, which the third neglected to do.

In the presence of a paraurethral passage, some of the virus may lodge therein, while the urethra itself is not primarily infected, owing to the cleansing effects of micturition. Some of the cases of apparently excessively long incubation have proved to be due to this cause, the infected follicle having caused no noticeable symptoms until the urethra itself was invaded by an overflow of germ-containing pus therefrom.

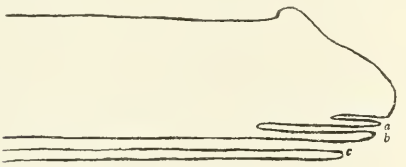

FIG. 1.—Illustrating a case of triple urethra; *a* and *b*, supernumerary urethræ; *c*, normal urethra.

I have seen quite a number of cases in my own practice (how many it is impossible to state, as all my records were destroyed by fire in 1904) of so-called double urethra and a very interesting case of triple urethra. I have been able to find but four such cases on record, those of Luxardo and Ward.

CASE I.—The patient, F. A., 26 years old, unmarried, was of good heredity and general health. He had suffered from one attack of gonorrhea, four years previously, which lasted two months. Six weeks before he consulted me (February 23, 1905) he had acquired gonorrhea. The acute symptoms had lasted but two weeks. Since that time he had had a slight, moderately thick, yellowish discharge on rising, but very little during the day. He had no pain on urinating, but some frequency during the day time only. He complained of pain in his loins and across the abdomen. He presented a moderate hypospadias, the urethra being only 1/16 inch from the lower edge of the glans, and of very small caliber as are all such urethræ. Above this, separated by a thin layer of tissue, was a second passage 1¼ inches in depth, and above this a third canal one-half inch in depth, both having about the caliber of a darning-needle, as shown in Figure 1.

There was a slight mucopurulent discharge, a few epithelial cells, and a moderate number of gonococci. The first glass of urine was cloudy and contained pus-shreds, the second glass was also cloudy. The treatment consisted of the injection of a solution of an organic silver salt in the anterior urethra, which he was instructed to continue three times daily at home, and instillations of a stronger solution in the posterior urethra, which I made every other day. On March 2 he no longer had any discharge even on milking the urethra but both portions of urine were still cloudy.

I did not see the patient again till April 22, he having continued the injections for three or four weeks after his last visit. At this date there was a very slight mucous discharge from the urethra on expression, containing principally epithelial cells, very little pus, and no gonococci. The first glass of urine was clear and contained a few small, floating shreds. The second glass was also clear. The middle urethra was normal but the superior contained a small amount of pus, with a few epithelial cells and a moderate number of intracellular gonococci. This passage was then treated with a 10 per cent. solution of silver nitrate by means of a blunt-pointed hypodermic needle and the case progressed favorably.

On October 3, he returned for a final examination, when there was no discharge from the urethra proper. The first glass of urine was clear and contained one shred consisting principally of epithelium with a few pus cells; second glass was also clear. In the upper urethra there was a very little moisture, containing mostly epithelium with some pus cells and what are termed secondary bacteria, but no gonococci. Had not this persistent gonorrheal infection of the supernumerary urethra been discovered and cured, this patient would have gone on reinfecting himself indefinitely as often as the true urethra was healed.

CASE II.—A very interesting case is that of J. H., 24 years old when first seen in 1899. At that time he had a very severe paraphymosis, which his physician had not tried to replace, following a gonorrhea of five days' duration. The urethritis proved obstinate until I discovered a paraurethral canal within the meatus at ⅛ inch distance. On slitting this open to a depth of ⅜ inch, apparently to the bottom, the gonorrhea healed promptly, leaving however a slight catarrhal urethritis which lasted several months, until he was treated for a chronic seminal vesiculitis, when the discharge entirely disappeared and the urine became perfectly clear with a very few minute shreds. His potency which had become almost nil was regained and he had good morning erections.

On October 27, 1906, twelve days after coitus, this patient came to me with a slight discharge, containing pus and gonococci. First glass of urine cloudy, second clear. Treatment for the first few days, organic silver injections six times a day, afterward three. Gonococci were present occasionally till November 30 when, on passing an acorn bougie No. 21, French, I found an obstruction at 3½ inches from the meatus which yielded rather easily. Directly afterward a large drop of pus appeared at the meatus. He had urinated just previously. His condition improved then steadily till on December 13 there was no discharge, the first glass was clear with very few shreds and the second glass was also clear. He took the beer test the next day and reported the evening of the 15. While waiting his turn he had to go out and urinate. I, of course, expected to find no discharge five minutes after urination, but on compressing the glans a thick drop of pus oozed out containing numerous gonococci. On urethroscopic examination I discovered a paraurethral canal ¼

inch from the meatus and about ⅛ inch left from the median line below, exactly at the site of the canal opened 6 years ago. A filiform bougie entered this to the distance of 1¼ inches. I immediately began injections of 10 per cent. argyrol solution to the bottom of this passage every other day and, as there was no improvement, a few days later entrusted the patient with self-treatment by means of a long, blunted hypodermic syringe twice daily, continuing the ordinary urethral injections.

No result appearing I changed the solution and subsequently used myself a 12 per cent. tincture of iodine, seeking to produce an adhesive inflammation from the bottom. This also proved futile and 10 per cent. nitrate of silver was resorted to. The urine cleared for three or four days, when again a drop of gonorrheal pus could be expressed. I then sounded the passage again with a filiform, and to my surprise, found a second passage 2⅛ inches deep, apparently a branch of the former, as I could find but one opening in the urethra. On introducing two filiforms of equal length, till they struck bottom, the one protruded nearly an inch beyond the other.

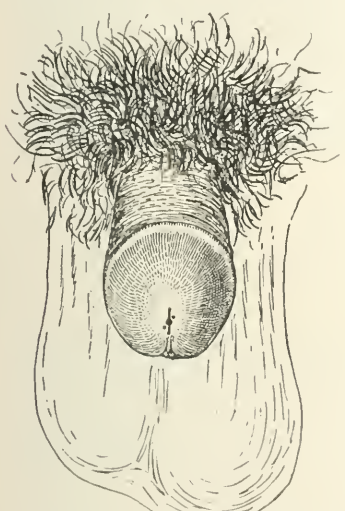

Fig. 2.—Illustrating Case V; the two dots alongside the meatus represent the follicular openings.

I believe this to be the explanation of the persistent infection, that the solution injected entered only one canal, probably generally the shorter. This was obviated by leaving the filiform in the shallower canal, when the needle could only enter the deeper one. Then the reverse tactics were employed. The urine cleared in a few days, but two or three days later pus with gonococci again appeared. With a two-bladed urethral speculum of my own design and Bierhoff's lacunar knife I then divided the canals nearly to the bottom, but the eighth-inch of canal left uncut, owing to the probe point, still give vent to pus with gonococci. This condition was overcome by treatment with lunar caustic fused upon a fine copper wire as described above. The patient then made a rapid recovery which has since proved permanent.

Case III.—Several months ago a third gonorrheal patient presented a similar canal ⅝ inch deep, just within the meatus and ⅛ inch left of the middle line below, but it was never invaded by the gonococci.

Case IV.—In February last an out-of-town dentist consulted me, ten days before his wedding, for a relapsing urethritis which appeared after every coitus. He had a slight hypospadias, the urethral opening being at the ordinary site of the frenum. At the usual position of the meatus there was a dimpling in of the epidermis about 3/16 inch deep and the caliber of a darning needle. Neither opening was infected. He passed the beer and nitrate of silver tests without showing gonococci and consummated his marriage. Up to date there has been no infection of his wife nor any recurrence of his former trouble. The latter fact supports the theory of Keyes that marriage "by allowing healthy, natural, unstimulated sexual relations" acts "as a curative agent in morbid conditions of the urethra, especially if there be any nervous element present in the case."

Case V.—G. T. C., February 11, 1908. First gonorrhea eight years ago; lasted several months. Ever since that time urination has occasionally been painful and the lips of the meatus are glued together. Present gonorrhea began in August, 1907, was apparently cured in one month, but ever since has had recurrence on drinking. He has slight pain on urination and tenderness in suprapubic region. Slight frequency. Mucopurulent discharge containing pus, epithelium and gonococci. First and second glasses a little cloudy. Prostate boggy and painful; expressed secretion contains pus. Treatment: Massage, injection and instillation of protargol. February 15: Mucous discharge containing pus, more epithelium and one pus cell with gonococci. February 17: Purulent discharge containing gonococci. On the patient's describing an uneasy feeling about the meatus I found, only after the most minute examination, an extremely fine follicular opening, into which the smallest probe-pointed epilation needle could be introduced with difficulty. This was located at the edge of the right lip of the meatus, about ⅛ inch from the lower commissure and was ¼ inch in depth. At the middle of the left lip there was a similar minute opening about 1/16 inch deep. The lower opening, on expression, exuded pus containing gonococci. Between these two openings, on each side, there was a furrow, much redder than the remainder of the urethra, extending inward about ½ inch. I expected to find on urethroscopic examination that these led into urethral follicles, but they proved to grow shallower till lost upon the surface. The appearance of the meatus is shown in the accompanying illustration, the two dots representing the follicular openings.

Both follicles were treated by electrolysis and on February 21 appeared to be healed. On February 23 the right follicle was again open and exuded pus containing gonococci on pressure and was again treated by electrolysis. On March 2 it still contained a little pus with gonococci, but the urethral discharge was mucopurulent and contained no gonococci. First glass a little cloudy, second practically clear. I then used a piece of fine wire instead of the needle and enlarged the opening by electrolysis so as to be able to introduce lunar caustic, fused upon a wire as described above.

On March 6 this obstinate little channel still contained gonococci and I again introduced the lunar caustic wire. After this treatment it healed definitely and the case then progressed rapidly to a cure which withstood the beer and nitrate of silver tests successfully.

Case VI.—P. I., twenty-six years old. First gon-

orrhea seven years ago; cured. Second gonorrhea two years ago. He had no symptoms since eighteen months ago, except a milky discharge after urination during the past year, until three months ago he suddenly acquired a thick discharge and painful urination, which have persisted until now. He has been married one year and his wife claims she is well, but will not submit to an examination. Examination shows a purulent discharge containing gonococci. Both glasses of urine cloudy. Seminal vesicles much dilated, prostate large and boggy, both very tender; expressed secretion is purulent. Just above the meatus there is a slight dimpling in, representing a rudimentary double urethra. On the right lateral wall of the urethra, three-eighths inch from the meatus, there is an inflamed urethral follicle, nine-sixteenths inch in depth, from which pus containing numerous gonococci can be expressed. The patient states that one month ago this portion of the penis swelled as large as an olive, so that the right lip of the meatus was doubled over the left. After two or three days there was a profuse discharge of pus and the tumor subsided. After incision of the inflamed follicle, followed by rectal massage and injection and instillation of an organic silver solution for one month the patient recovered. It is a problem whether this patient had had a latent gonorrheal prostratitis since his last infection or had been reinfected by his wife.

METHODS AND RESULTS OF DRAINAGE IN 22 CASES OF ABSCESS OF THE APPENDIX.*

BY R. M. HARBIN, M.D.,

ROME, GA.

MODERN surgery has put forth the dictum that pus in the appendix is one of those sequelæ that should never have occurred, for the patient must needs be operated on before the stage of suppuration. Be that as it may, cases of appendical abscess do occur. It is easily understood why many cases in the country either proceed to the formation of abscess or else develop into diffuse suppurative peritonitis, as immediate operation may be out of the question. I may say, incidentally, that fourteen out of the twenty-two cases herein reported were seen out of the city, in consultation.

It is rare that the average physician in the country fails to diagnose properly a case of appendicitis, but, not unlike the surgeon, he cannot always diagnose the different stages of the pathological process.

*Read at semi-annual session of the Seventh District Medical Society, Cortersville, Ga., Oct. 14, 1908.

In the absence of proper facilities, it is better to adopt the Ochsner régime, and the Fowler position, pending consultation. Of the nineteen cases seen in consultation, four proved to be advanced cases of diffuse suppurative peritonitis, exceeding forty-eight hours' duration, with a mortality of 100 per cent.; while in one case of my own, a diagnosis of perforation was made and the abdomen was drained eight hours later with recovery. Mortality rates increase in geometric proportion to the number of hours after perforation, and statistics of recoveries possess no value, when the date of perforation is not given. In the four cases referred to rupture was believed to be primary, and occurred in those who gave no history of previous attacks. The presence of exudative remains of a previous attack gives a certain degree of protection to the peritoneum from the débris of a sloughing appendix, for those fulminating types are usually found in primary attacks.

If we could trust the strength of the walls of adhesions set up by Nature, it would be wiser to defer drainage until the patient undergoes a sort of autoinoculation of bacterial vaccines, which offer a certain degree of protection against chance infection while opening the abdomen in these cases, and this rationale would explain the wisdom of Ochsner's procedure under certain conditions.

In primary rupture, the ill-prepared patient is drowned, so to speak, in a flood of infection. As a rule, we do not have diffuse or general peritonitis late in the attack of appendicitis, for the phagocytic elements will protect the patient, if the escape of infection is gradual enough. While the infection is thus being taken care of, it would be decidedly unwise to invade the peritoneum during this particular stage of the disease. The refinement of a diagnosis of such a condition is well nigh unattainable, and while we are waiting for the walling-off process, the case may be merged into one of diffuse peritonitis. As infection gravitates toward the right iliac fossa, the disease becomes more securely walled off, and may be temporarily trusted to Nature.

If the pulse and temperature decline, it may be presumed that Nature is taking care of the infection, notwithstanding the presence of an indurated mass.

Bier's method of treatment by artificial hyperemia would seem to explain the favorable effects of poultices, which I prefer to the use of the ice-bag.

The position of the incision is to be determined by the location of the indurated area, and should be made below this mass, toward the anterior superior spine of the ileum, somewhat parallel to Poupart's ligament; for the caput coli usually overrides the abscess. When the abscess has developed toward the middle line, it should be invaded behind the colon, if practicable.

Short incisions were the rule in these cases, and when the angles are tightly packed, sufficient space is left for a loose wick of gauze. It is not necessary that the exit of a pus cavity should be as large as its greatest diameter, and long incisions do undoubtedly favor the subsequent development of hernia.

It may happen that the parietal peritoneum becomes adherent to that of the colon or intestines; and if such be the case, entrance should be made nearer the anterior superior spine. Having opened the peritoneum and introduced a protective gauze packing, the finger should follow the abdominal wall until the indurated mass is reached, and then

with the finger a process of blunt dissection should be begun, hugging the posterior wall of the abdomen until the abscess is reached. If the abscess is larger, the patient should be turned on the right side, and the exit enlarged. The wound having been mopped out, a careful search should be made for concretions, most offensive condition ever seen in surgery. The outer wound should be mopped and cleaned with peroxide of hydrogen, as needed. There can be but little danger of spreading infection by changing the packing after the third day, where the direction of the sinus is well known, and drainage is facilitated.

Fig. 1.—The Ventral Decubitus.

remains of the appendix, etc. A piece of plain gauze, one and one-half to four inches wide, with a double layer, should be carried with the finger to the bottom of the cavity. If the surgeon has any respect for the olfactory sense, iodoform gauze will Rarely there may be circuitous tracts to drain, when it is better to leave the packing, and as a rule, in children it is better to leave the gauze undisturbed. After the first dressing, the removal of gauze need not be specially painful, and it should be changed

Fig. 2.—The Fowler Position.

not be used, for appendical pus and iodoform add a reciprocal intensity to the stench, and in two cases of children, marked toxic symptoms were noted.

Perhaps the most unsurgical custom prevails in allowing a soppy piece of gauze to remain in a wound for a period of several weeks, making the every two or three days. Changing the gauze furnishes a sort of mopping for the wound. The débris of a sloughing appendix, etc., cannot escape where the packing is not changed until a process of fermentation reduces such material to a liquid state. In one case of a child, a false passage pro-

duced a secondary abscess, where the first packing was attempted without anesthesia. In only two cases was it found necessary secondarily to enlarge the exit of the abscess cavity. Too much manipulation will spread infection, and may aggravate a condition we are trying to relieve; and to relieve one accumulation of pus only favors the development of another, for pus spontaneously proceeds in the line of least resistance. One of the most troublesome cases I have had was, in my opinion, due to too much manipulation.

Perhaps postural methods in aiding drainage are not utilized as often as their merits would warrant. I have found the lateroprone and ventral positions (Fig. 1) are of material assistance, for these facilitate other methods of drainage. In the management of these cases the patients were not allowed the left lateral position for the first three days, and even after that time it is unnecessary and may be unwise. For the first four hours the patient was placed in either a ventral decubitus or right lateral position, changing as the comfort dictated. Then later the dorsal or the lateral and intermediate positions were adopted. All of these positions at times were combined with the Fowler position (Fig. 2).

In using the semierect position it is necessary to have support under the buttocks, or a board at the foot of the bed for the feet. It proved unsatisfactory to instill normal salt solution, according to Murphey, for the patient was kept constantly wet, and the presence of a small catheter seemed to excite intolerance on the part of the rectum. In fact, using four ounces every three or four hours seemed to gain a greater amount of absorption while in the semierect position.

The amount of seropurulent discharge is directly proportionate to the chances of recovery, for it is desirable not only to give exit to pus in diffuse peritonitis, but to provoke a reverse flow of serum out of the wound—a form of autoirrigation. Morphine should be used if needed, for restlessness of the patient seriously interferes with the process of localizing infection.

Restricted quantities of liquid food may be allowed in ordinary cases, but when there is diffuse peritonitis nothing should be given by the stomach for twenty-four to forty-eight hours. The bowels should be kept in a passive state for forty-eight hours, after which time one or two grains of calomel may be given in sixth grain doses every hour, to be followed by a turpentine enema. The use of purgatives is frequently overdone.

Of the twenty-two cases reported, the youngest was four and the oldest fifty, the average 24.6 years. Eight cases gave a history of previous attacks. Of the six cases giving a history of trauma, only one gave history of a previous attack which was also traumatic. Nine attributed acute indigestion as a cause, and seven were negative. Of the nineteen frank abscess cases, the average date of operation was 7.9 days from the beginning, the earliest having been on the third and the latest on the nineteenth day of the attack.

Peculiar location of the abscess was noted in two cases. One was retroperitoneal, and burrowed through the muscles of the right lumbar region, at which point it was incised and drained. This case was reserved for another operation, but passed from observation. Case 18 developed a small abscess near the middle line, and there were adhesions to the bladder, which was inadvertently punctured during operation with no harm resulting. In case 13 the abscess burrowed through the anterior abdominal wall, and the sinus persisted for six months; the patient has since remained well. In Case 11 the sinus discharged intermittently for eight months and then remained well. Barring these exceptions, in no case has there been a recurrent abscess. Case 14, a young unmarried woman, aged twenty-five, ended fatally three weeks after operation, no relief from septic symptoms being gained by drainage.

Conclusions.—1.—Statistics of recoveries from drainage of cases of diffuse peritonitis are of no value unless the date of the perforation is known.

2.—In the absence of proper facilities, it is better to adopt the Ochsner procedure and the Fowler position, pending consultation.

3.—The doubtful propriety of waiting for the walling off process, may merge a certain number of cases into a diffuse form of peritonitis.

4.—Deferred operations, under favorable conditions, give the patient time to undergo a sort of autoinoculation with bacterial vaccines.

5.—The uncertain course of peritonitis argues for immediate operation.

6.—Infections low in the right iliac fossa can safely be trusted to nature.

7.—Short incisions and few manipulations should be the rule.

8.—As a rule, it is unsurgical to leave the same gauze in the wound over four or five days.

9.—The right lateral and ventral positions are of great value in supplementing other methods of drainage.

10.—Drainage in diffuse peritonitis should not only give exit to pus, but should provoke a reverse current of serum out the wound.

11.—Intermittent injection of normal salt solution seemed to gain a greater amount of absorption in the rectum than the instillation method.

12.—In well defined abscess cases there was a mortality rate of 4.5 per cent.

THE CONSERVATION OF HEARING IN THE RADICAL MASTOID OPERATION.

By SEYMOUR OPPENHEIMER, M.D.,

NEW YORK.

In the simple mastoid operation where the antrum is exposed, pus and granulation tissue removed, and necrosed or carious bone in its vicinity eliminated, the relation of the operative procedure to the hearing power need not be considered, as the conducting mechanism is not in any way interfered with, and what changes occur in this respect are the result of the morbid process in the middle ear, which is corrected by the operation. In the so-called radical procedure, however, where diseased bone areas are removed and the natural cavities in the temporal bone are converted into one large single chamber, with the removal of the malleus, incus, and tympanic membrane, it has been the accepted habit of many operators to pay little or no attention to the preservation of hearing from the surgical aspect, and in a considerable number of cases where there was a possibility of retaining what hearing was left, or possibly even obtaining some improvement following operation, it has been sacrificed in the endeavor to remove all diseased or apparently diseased tissue and thus obtain a cessation of the purulent discharge.

The objects of the radical operation or its various modifications, which will only be considered in this

respect, are actually three in number, viz., the saving of life, the cure of suppuration, and the preservation of hearing. When the operation is performed with the first object solely in view, that of saving the life of the individual, the question of hearing in relation to the procedures employed must of necessity be relegated to the background, but when such a procedure is carried out in order to prevent later serious consequences affecting either the health or even the life of the patient, but with the main object at the time of obtaining a cessation of the chronic suppuration, it is not only justified, but under present advances essential, that the most careful attention be paid to the preservation of the hearing in every respect.

In many minds, the radical operation implies not only the removal of all diseased mastoid tissue, but the entire cleaning out of the tympanic cavity, so that all these parts will ultimately be covered with a dry layer of epithelial tissue; but it is undoubtedly becoming clearer that tissue in the tympanic cavity which has heretofore been removed in its entirety to accomplish this aim, might in some cases be allowed to remain after the focus of the suppuration higher up has been removed. With this end in view, a bit of epithelium here and there, or possibly an ossicle, can be allowed to remain with safety and be the means of preserving a considerable degree of auditory acuity that would otherwise be lost. Not that any markedly diseased tissue should be allowed to pass unchallenged, but such parts should be carefully investigated, and on account of the great recuperative power of the soft tissues of the tympanum, it is undoubtedly good surgery to save as much as possible to attain this aim. The object of the modern mastoid operation for the cure of chronic suppurative otitis media should not be to eliminate and obliterate all that is possible of the temporal bone in this particular region, but the aim should be, as far as is consistent with the safety of the patient, to restore the auditory organ to a condition as nearly perfect as possible and, with due respect towards this, with consideration of its function.

The effect of the radical operation on the hearing varies greatly in the hands of different operators; but in the majority of cases it can be safely stated that it becomes still more impaired following operation, while in a very small minority, more or less improvement takes place. Many cases, however, in this respect, are not properly tested previous to operation and sufficient stress is not laid on the proper selection of cases as regards this aspect of the question. If there are pathological alterations in the inner ear, it is very apparent that operative procedures will not improve the hearing in the slightest degree, while on the other hand, where there is extensive destruction of the tissue in the attic of the tympanum, with complete loss of the incus and the membrana tympani extensively destroyed, the same loss of hearing previous to operation must remain unchanged thereafter. It is essential, in order to obtain results of any value in this way, that care be exercised in selecting cases for operation from this point of view to take those in which some hearing power of sufficient utility to be of value remains and to see to it that none of the conditions previously stated are present, for as has been shown by Heath, individuals with deficient sensibility of the labyrinth do not hear when the membrana tympani has been destroyed and in such instances no improvement will follow operation.

When great care is exercised in preserving as much as possible of the tissues of the middle ear in relation to the conduction of sound, even if marked morbid changes have taken place here, it will be found that a considerable gain in the hearing may be accomplished, provided of course that tests previous to operation show that no alterations have taken place in the labyrinth. In the selection of cases where some beneficial result can be anticipated as regards the hearing function, the continuity of the ossicular chain must be carefully taken into consideration; and while in a constantly increasing number of cases where the ossicles have in greater part been destroyed, a considerable improvement of hearing can be obtained, yet when the malleus or incus, and especially the latter, has entirely disappeared, as is frequently the case, but little can be anticipated in the way of improving the hearing, whatever care be used in the operative procedure.

A distinct factor in the preservation of the hearing is the adoption of early operation in those cases where topical measures used for a reasonable period of time prove of no value. That this is so is made evident by the operative procedure anticipating the further destruction of tissue and thus conserving the hearing to that degree, while at the same time certain important structures may be saved that would undoubtedly later become involved in the morbid process and be in greater or lesser part destroyed.

The more perfected the technique of the mastoid operation, the more will the hearing be conserved, other things being equal; and the greater the experience of the operator, the greater will be the care exercised both in the selection of cases and in the discrimination of tissue to be saved during the course of the operative procedures. The perfection of the technique, which implies the utmost care both during operation and in the postoperative treatment, undoubtedly counts for much in this respect, and of the many aspects of this phase of the question, none is more important than that during any operative procedure here all parts should be absolutely visible, so that every move that is made can be clearly seen, and therefore that all bleeding be controlled, so that the relation of the various parts of the operative field may be constantly under the direct vision.

While the antrum is the most important point as regards the focus of the pathological changes, the tympanic cavity proper, with its contents, is the prominent factor concerned with audition so far as operative procedures are concerned, and it is essential, so far as is consistent with the morbid conditions present in the individual case, that all parts concerned in the conduction of sound waves be interfered with as little as possible. Should the usual hearing tests show that the ossicles, whether partially removed or remaining in their entirety, are of some value in the conduction of sound previous to operation, much will be gained by their retention, and even if superficial necrosis here exists in part, it will be found that after the original source of the pus supply has been removed, healing will take place and this tissue can thus be ultimately saved, instead of being uselessly sacrificed in every case that is operated upon.

As far as the membrana tympani is concerned, it is unnecessary to remove it in its entirety in many cases, and if adhesions are freed, should such be present, a small perforation is enlarged for free drainage, or if necessary, and this is not infrequently so, a large incision is made in other portions, so that drainage can be readily carried out, it will materially

aid in retaining much of the auditory acuity that would otherwise be lost. A matter of considerable importance in all operations in this region, in which care is exercised concerning the hearing, is the avoidance of the tympanic cavity so far as the indiscriminate use of probes and similar instruments is concerned, as much damage can be done with careless instrumentation here, and while careful probing in order to ascertain the condition of the osseous structures is perfectly proper, it should be performed as rarely as possible and with the utmost care.

While all granulation tissue in the antrum, aditus, and mastoid cells should undoubtedly be thoroughly removed, that in the tympanum itself should be dealt with most carefully and allowed to remain unless extensive tissue destruction involving the malleus and incus is present. In that case it should be removed, especially around the opening of the Eustachian tube and in the neighborhood of the posterior wall. As a rule, in this location granulation tissue presents a protective barrier against the further infection of the tissues, whether soft or osseous, which it covers and the removal of such a protection leaves the parts exposed to further infection and serious harm, while at the same time too forcible destruction of granulation tissue on the interior tympanic wall is attended with a serious risk of damage to the internal ear.

In addition to the careful preservation of all healthy tissue wherever found during the course of the operation, unless it becomes necessary to sacrifice it to some extent over limited areas in order to obtain necessary drainage, the mucous membrane lining the walls and covering the ossicular chain should be carefully preserved, not only when it appears to be healthy, but even when it is infiltrated and thickened, as these morbid changes disappear within a short time after operation and the mucosa then resumes its normal appearance. In practically every instance of chronic aural suppuration, the main focus of the pus-producing area is the antrum, and if all diseased tissue be eliminated here and in other portions of the mastoid structures, which are usually involved to a greater or lesser extent, it will undoubtedly follow that the drainage areas lying below these parts, which are constantly being irritated by the pus flowing over them, will heal rapidly when such a source of irritation has been removed.

The antrum is therefore the most important area in the temporal bone so far as these pathological changes are concerned, and is the primary objective point in all operative procedures. But while much has been gained by the removal of all diseased tissue at this point, it is essential to success that drainage be obtained from it while healing is taking place and the parts are undergoing resolution, and to accomplish this it is essential that there be no obstruction from this point, either in the aditus or tympanic cavity proper.

In some cases, in order to accomplish this object, it is absolutely necessary to remove entirely all the contents of the tympanum irrespective of the effect upon hearing, but in many other instances it will be found that with a little care as free drainage as is desired may be obtained and yet the tympanic contents can be preserved, so that there will be a gain in the hearing acuity following operation.

In those cases with the membrana perforated in relation to the attic space and the suppurative process apparently localized in this regian, especially if cholesteatomatous elements be present in the aural discharges, it will usually be found that this portion of the tympanum simply acts as a drainage deposit for the real pathological process higher up in the antrum.

When the important structures in the attic are, however, seriously compromised by the long continued suppuration, it seems the better policy to remove them and clean out this part of all diseased tissue, as in such cases the hearing is practically destroyed, or will become so, if the diseased tissue is allowed to remain here. In some few cases of so-called attic suppuration, however, sufficient drainage can be obtained, if the head of the malleus and the incus are not seriously necrosed, to allow of a restoration of the tissues to normal; and if these cases show even a small degree of hearing previous to operation it will be found that this has been greatly augmented later on after the source of the purulent discharge has been eliminated.

45 East Sixtieth Street.

MEDICAL EDUCATION IN RUSSIA.*

By LEON LOURIA, M.D.,

BROOKLYN, N. Y.

ATTENDING PHYSICIAN, JEWISH AND GERMAN HOSPITALS, BROOKLYN, N. Y.

After contemplating the matchless superiority of the famous medical centers of the Old World, it would be a difficult task, indeed, to arouse your interest in the topic that your chairman has given me the honor to present this evening. I shall endeavor to throw some light upon certain little understood phases of medical education in the Empire of the Czar. It is a giant's stride from Berlin to Moscow, and to many the journey would seem like a voyage from the enlightened present into a medieval past. But this is not so. To those who have kept in touch with the uplift of the world during the past few decades Russia has loomed large upon the intellectual horizon. The generally prevailing misconception of this advance is to be attributed to an unfamiliarity with the language of the Slavs. Yet the land that has given to literature a Tolstoi, to art a Verestchagin, to music a Rubinstein, to chemistry a Mendeleef, to neurology a Bechterew, and to experimental medicine a Metchnikoff and a Pavloff, certainly needs no apologist.

As an illustration of the prejudice that frequently distorts a correct appreciation of Russian enlightenment may be cited the following quotation from the little volume entitled "Glimpses of Medical Europe," by Ralph L. Thompson, Professor of Pathology in St. Louis University, School of Medicine: "From a medical point of view our visit to St. Petersburg is scarcely worth the writing, for we saw little that was medical. However, we will mention the journey to prevent others from going the same way." With apologies to the learned author, and with your kind indulgence, I shall try to delineate the present status of medical education in darkest Russia. I hope I may be pardoned for still cherishing a fond regard for this institution in my native land. Indeed, I shall always look back with pride to my Alma Mater, the historic Medical University of Moscow. It is particularly fortunate that the paternal attitude of the Russian Government, so sharply criticized and energetically resisted in other

*Read before the Section on Medicine, Medical Society of the County of Kings, October 12, 1908.

fields of activity, has successfully maintained itself in this most important field of medical education. This has always been supervised and controlled by the Government. Indeed, the Minister of Public Instruction has full charge of all schools, from the primary grades to the university. This insures a uniformity of educational practice throughout the Empire, and the curricula are identical in the University of Dorpat, the nearest neighbor of the illustrious models of German teaching, and in the University of Tomsk, thousands of miles away in Siberia. There are no private institutions of medical teaching, supported by the endowments of kind but frequently interested benefactors, nor are any of the schools established with professorial chairs auctioned off to the highest bidders or assigned to the largest investors. There are no postgraduate schools financed by the liberal friends of the professors.

Most of the Russian medical schools are not of recent origin, but are firmly rooted in the distant past. The medical department of the University of Moscow was founded as a school for surgeons as far back as 1706 by Peter the Great, and was established as a distinct medical faculty in 1755. Toward the western confines of the Empire the University of Dorpat was founded in 1802 as a Russian institution by the Emperor Alexander I, although it may trace its early history to the year 1632, when it was established by the Swedish conqueror, Gustavus Adolphus. On the eastern steppes of European Russia, in the land of the Tartar, the University of Kasan first saw the light in 1804. The following year the University of Charkoff was founded, while that of Kieff followed in 1834. The old Polish University of Warsaw, that had been suppressed in 1830, was reorganized under the Russian régime in 1869. In 1888 the University of Tomsk was reared on the distant plains of Siberia, while in the far north Helsingfors arose in the land of the Finns. The youngest in the family of medical faculties is the school at Odessa, founded in 1899. Last, but not least, may be mentioned the famous Military Medical Academy at St. Petersburg, founded in 1798, while within the past few years a medical school for women has been established in the Russian capital. To these must be added the Imperial Clinical Institute for postgraduate study, founded by the Princess Helène in 1885, and the Imperial Institute for Experimental Medicine, established in 1891.

The requirement for admission to any of the Russian medical schools is the possession of the certificate of maturity, granted by the Classical Gymnasium after eight years of study. This certificate is the equivalent of a little more than our high school diploma. In connection with this, it may be stated that no person younger than nine years of age is admitted to the gymnasium, while it takes no less than eight years for the completion of the course. In no manner can this period be curtailed by the skipping of classes or the election of easy subjects in the curriculum.

The preparation for study of medicine is a matter of vital importance to the Russian. He who would enter the guild of Æsculapius must needs be fitted for it by native aptitude and mental endowment. The medical career is determined upon early in the boy's life by his guardians, and he matriculates in the gymnasium with the medical school as his ultimate goal. The certificate of maturity is a guarantee of his fitness for the further pursuit of professional studies. The superiority of this demand for proper preliminary training, when compared with the practice now largely prevailing in this country, as evidenced by perfunctory regent's examinations, is too obvious to need further comment. America is only beginning to emerge from its anomalous system, and may well take a hint from the barbarous Russian.

At no time in the history of Russian medical education has the course been less than five years The first two of these are devoted to Botany, Zoology, Physics, Chemistry, Anatomy, Histology, and Physiology. This constitutes the semi-academic course, which must be successfully completed before the student can enter the final three years of his curriculum. This is devoted to the purely practical subjects, and constitutes a very elaborate course of studies, with unsurpassed laboratory and clinical facilities. All Russian medical faculties have their own large hospitals connected with them, while the doors of other city hospitals are open to the medical students. This is another practice from which America may well take example. The Russian hospitals are municipal institutions, and are under the control of the Ministry of the Interior, which cooperates with the Ministry of Public Instruction. Neither teachers nor students are at the mercy of lay governing boards or of their subordinates, the hospital superintendents. The management of the hospital is in the hands of the physician-in-chief, who alone is capable of appreciating the full value of the hospital material for didactic purposes.

After completing ten semesters, or five full years of study, and after passing academic examinations in the various subjects, the student is required to pass a State examination before he can receive his license to practise medicine. This is conducted by an examining board assigned to each of the medical faculties by the Minister of Public Instruction. The examining commission consists of five members, and the programme of the examination is divided into five main parts. Each member of the board selects from the medical faculty the professors who are to conduct the examinations in the respective subjects, he himself acting in a supervisory capacity. To illustrate the wide scope of the examinations, one need only consider the variety of subjects that enter into it. In the first part, examinations are held in Descriptive Anatomy, Histology, Pathological Anatomy, Pathological Histology, Topographical Anatomy, and Operative Surgery. Examinations in these subjects are practical, requiring of the candidate actual laboratory demonstrations and operations on the cadaver. The second part of the examination covers Physiology, General Pathology, Medical Chemistry, Pharmacy, Pharmacognosy, and Pharmacology, Prescription Writing and the use of mineral waters. The third group includes Special Pathology and Therapy, Nervous and Mental Diseases, Dermatology and Syphilis, Pediatrics, and Practical Demonstrations in the internal medical, skin, and children's clinics. The fourth group covers Surgical Pathology, Fractures, Luxations, and Bandaging, Ophthalmology, Obstetrics, Gynecology, and Practical Diagnosis in the surgical, ophthalmological, and gynecological clinics. The fifth group includes Hygiene and Medical Police, Legal Medicine, Toxicology, and Diseases of Domestic Animals. The examinations are oral, the candidate drawing by lot a number, and answering the questions corresponding to it on the examination paper. Having passed the State examinations, the candi-

date receives a diploma as physician, which entitles him to practise throughout the Empire. The title of Doctor of Medicine is not granted except after a special supplementary examination, and the presentation of a suitable thesis, representing a special line of independent research or experience. Such thesis must be defended at a public hearing, the opponents being assigned by the dean of the medical faculty among the teachers of the respective branches, and only the successful defender of his thesis is accorded the highly prized degree. This confers its special privileges, not only in private practice, but as a passport to governmental employment or academic appointments. Such academic appointments are numerous, and are prizes much sought after. They include the position of professor —emeritus, ordinary, and extraordinary, privatdocent, prosector, laboratory worker, and clinical assistant. In the Imperial Military Academy of St. Petersburg there are thirty-three professors, who are assisted by 189 of the above mentioned auxiliary workers. The honor students are eligible for the governmental scholarships, comprising two years of special study in foreign universities, to be followed by possible appointment as instructors or privatdocents.

The Government bears the burden of the maintenance of the medical schools, the students paying the nominal sum of $50 per year. In the Imperial Military Medical Academy of St. Petersburg instruction is absolutely free, but the student is bound to serve for four years after graduation in the army or navy.

In addition to her regular university medical schools, Russia provides a unique system of less elaborate institutions for the training of medical assistants. These fulfil an important need in the Empire, with its vast distances and its enormous and heterogeneous population, mainly rural. These medical assistants are termed "feldschers," and so peculiar is their rôle in the community, that this subject cannot be passed over without devoting a few moments to their consideration. The scarcity of physicians in Russia has necessitated the existence of this special class of medical men, for whom a distinct course of study has been provided in forty-one different schools, established throughout the vast territory of the Czar. For entrance into these schools a grammar school education is required. These subordinate medical schools, of which there are twenty-three for men and eighteen for women, are connected with hospitals, which are municipal institutions owned by the Government or established and supported by the Zemstvos or territorial assemblies, with the sanction of the national Government. The Zemstvos, which are local representative bodies existing in almost every province, provide for the medical needs of their constituents by employing physicians and feldschers and assigning them to districts the size of which depends upon the density of their population and the financial resources of the central body. Thus Russia provides an elaborate system of free medical visitation to the needy poor. On account of the sometimes enormous size of some of the districts it is impossible for the physicians to attend personally every patient who is not able to visit the district dispensary or hospital, so that the duty falls upon the feldschers to do this work. One can realize the importance of this task only when appreciating the fact that one-half of the population is still treated solely by the feldschers. This form of medical aid is by no means of a low order; it is rendered by men and women specially trained for the task by three or four years of theoretical and practical study in the hospital wards. These schools are somewhat analogous to our Training Schools for Nurses, with this difference, that, while we require from our nurses only an intelligent reporting of the patient's condition and the carrying out of our orders, the feldscher is trained to render medical aid independently, calling upon the district physician for counsel and assistance only in cases of grave severity.

Another branch of subordinate medical education comprises eight midwifery schools connected with the large lying-in hospitals in the chief cities of the Empire. The preliminary grammar school education required for matriculation, and the elaborate course of theoretical and practical obstetrics, serve to produce a body of intelligent accoucheuses. Although their training is confined mostly to this special branch of medicine, the practical experience received during their course of study makes them more efficient than many a physician, whose obstetric training consists of a perfunctory course of lectures and attendance upon one or two confinement cases. Their superiority and reliability in the lying-in room may be appreciated when contrasted with the ignorant ministrations of our American midwives, who easily obtain their license upon the payment of a small fee and the presentation of a testimonial of two friendly physicians.

In Russia the status of the physician is quite different from that which is generally recognized in most other nations, including America. His activities are not strictly confined to the purely technical duties of his calling, but have a far-reaching social and political influence. He, above all others, is fitted to bear the torch of progress. In the cosmopolitan atmosphere of the university he has come in contact with representatives from the most widely scattered provinces of the Empire; he has imbibed the spirit of liberalism, and his eyes have been opened to his own opportunities and those of his fellow townsmen. Little wonder, then, that when he returns to his birthplace these latter regard him with peculiar reverence. He is not only a healer of men, but also their liberator; he has returned to remove the shackles of ignorance that bind them and to become a powerful factor in the revolutionary movement. His counsels are sought in the local assemblies of the Zemstvos, and he frequently becomes the leader in the promulgation of local reforms. Is he not true to his calling who extends his professional skill from the diseased individual to the diagnosis of the ills that afflict the body politic, which is no more than a larger aggregation of biologic units? It is therefore not at all strange that in the awful tumult that is shaking the foundations of the Russian bureaucracy the disciples of Hippocrates are taking no insignificant part.

From the social viewpoint the physician is an important member of the Russian community, and more so than in most other countries. His calling is not prostituted to the level of a commercial pursuit, but is regarded as above the mere valuation of pieces of gold and silver. It is for this reason that there is no stated medical fee in Russia, for the physician is paid according to the value set upon his services by the patient, and this is small or large, depending on the means and gratitude of the latter. In addition to this, it is not uncommon for Russian physicians to receive gifts, amounting in many cases

to thousands of rubles per annum. In many instances physicians are employed by families at a definite annual salary.

As the Russian medical student looks forward to his future field of activities, he does so with full consciousness of the manifold opportunities of private and public service that are open to him. Aside from the private practice of medicine, there are the positions of public sanitary officer, of district visiting physician to the poor, and of physician to one of the numerous industrial establishments. The last position is one that factory owners are compelled by statute to maintain.

Although only a small portion of Russian medical literature reaches the outside world in the form of translations and abstracts, it is nevertheless quite extensive. A large army of medical writers find a suitable outlet for their literary efforts in sixty medical journals published in different languages throughout the Empire. These journals serve also as the mouthpieces of the sixty-seven medical societies established in the largest cities of the provinces. There is also a national body similar to our own organization, founded in 1883 in memory of the illustrious surgeon, Pirogoff. This society holds its meetings every two or three years, and the program is elaborate. In addition to those devoted to the usual medical topics, there are special sections assigned to military, to territorial, to industrial, and to mining medicine, a special section occupied exclusively with the important problem of infant mortality, and still another engaged in the discussion of the social status of physicians. Such a comprehensive and manifold programme reflects as a mirror the activity of Russian medical men. It clearly indicates that the Russian medical mind is not narrowly concentrated only on questions of clinical observation and medical research, but that the broad and important side of preventive and social medicine is fully appreciated and cultivated by the medical fraternity.

Without a further tax upon your kind patience I shall conclude, trusting that in my rather condensed sketch I have vindicated in your eyes Russian medical education, and have secured for the Russian medical diploma a merited and just appreciation.

249 Hewes Street.

THE HEMOLYTIC PROPERTIES OF CANCER SERUM.*

By A. S. BLUMGARTEN, M.D.,

NEW YORK.

The following paper is intended as a contribution to the study of the diagnostic value of the hemolytic power of the blood serum in persons suffering from cancer. Crile has recently stated that the serum in cases of cancer yields a characteristic reaction in practically 100 per cent. of the early cases, and in 85 per cent. of the advanced cases. On the other hand, Weil asserts that the results are characteristic in only 40 per cent. of the early cases, and in only 50 per cent. of the late cases. The method used by both of the observers was in principle identical, though differing in minor details. It was with the object of investigating these discrepancies that the present study was undertaken.

The method employed was that first used by Weil in his experiments with the serum of tumor dogs, and subsequently applied by him, and then by Crile, to the study of human disease. It depends on the principle that the serum of carcinoma cases is hemolytic for the red cells of normal individuals, but distinctly less so for the red cells of the same individuals, or of other carcinomatous individuals. Inasmuch as it has never been adequately described, it is here given in detail.†

From a number of individuals, including preferably an equal number both of ascertained cases of cancer and of other cases, preferably normal and designated as controls, blood is withdrawn. A ten cubic centimeter aspirating syringe is used, the best for the purpose being those made entirely of glass or of glass with metal piston. The plunger should be lubricated with vaselin to prevent rapid clotting. The best needle to use is one made of platinum-iridium, inasmuch as it can easily be sterilized by heating to a white glow in the flame of an alcohol lamp. The arm of the patient is cleansed at the elbow, and a bandage is applied above. After sufficient blood has been aspirated from one of the veins, two cubic centimeters are expelled from the syringe into about six cubic centimeters of a solution composed of 0.4 grams each of sodium chloride and sodium citrate in one hundred cubic centimeters of distilled water. The remainder of the blood is rapidly expelled into one or two test tubes, which are then laid almost flat in order to give a clot with a large surface area. Within a few hours, the clot will have expelled from three to six cubic centimeters of serum, which may then be poured off for use in the tests. If the serum is mingled with corpuscles, it may be cleared by centrifugalization. The blood which has been drawn into the citrate solution does not clot, and is at once centrifugalized. The corpuscles are washed three times in 0.85 per cent. sodium chloride by successive centrifugalizations, in order to free them from serum. The centrifugalized cells are finally made up into a 20 per cent. suspension in 0.85 per cent. salt solution. This is most easily accomplished by centrifugalization in graduated tubes, with the addition of salt solution to the sediment to make up a suspension of the required strength. The corpuscles and the sera from various cases are then ready for use.

The tests are performed as follows: A series of small test tubes, six to eight millimeters in diameter, and six to eight centimeters in length, are arranged in racks bored to hold a dozen in line. Each serum is tested against all of the corpuscle emulsions, ordinarily three from cases of cancer and three from controls. In case sufficient blood has been withdrawn for all six patients, this will give thirty-six tubes. The mixtures are made as follows: To one-half cubic centimeter of each serum is added one-tenth cubic centimeter of each of the corpuscle emulsions. The object of making the mixtures in these proportions is to dilute the sera as little as possible, in order not to diminish their hemolytic power, which is rarely very strong. The corpuscles constitute approximately 3 per cent. of the serum-corpuscle mixture. One-tenth cubic centimeter of each of the corpuscle emulsions is similarly added to one-half cubic centimeter of 0.85 per cent. sodium chloride solution, as a control series. The racks are now placed in the incubator for two hours, and for twelve hours in the icebox, after which the results may be read off. Tubes in which hemolysis has occurred are at once evidenced by their "laked" or reddish color, as compared with

*From the Pathological Laboratory of the German Hospital.

†For the method I am indebted to Dr. Weil.

the salt solution controls of the corpuscles. Such tubes are designated as positive (+). Tubes in which the corpuscles have undergone no change are designated as negative (—). If in a series of tests with a given serum any of the cancer corpuscles are laked, such a serum is positive for cancer corpuscles; similarly of normal corpuscles. The results may be grouped into four categories, as follows:

1. Serum fails to hemolyze cancer corpuscles, but hemolyzes control corpuscles (— +).
2. Serum hemolyzes both cancer and control corpuscles (+ +).
3. Serum hemolyzes cancer corpuscles, but not control corpuscles (+ —).
4. Serum hemolyzes neither control nor cancer corpuscles (— —).

In case a serum falls into group 2, it may be further tested in a series of higher dilutions, in the attempt to weaken its lytic action sufficiently to eliminate it for one group of corpuscles, while retaining it for the other.

The sera and corpuscles tested in the manner above described included twenty-five advanced cases of cancer, forty of various other diseases, and ten normal cases. The results of the reactions may be summarized as follows:

	1 — +	2 + +	3 + —	4 — —
Cancer	18	0	0	7
Other diseases	4	0	2	34
Normal cases	1	0	0	9

Group 1 conforms to the type described by both Weil and Crile as a "positive" reaction, and contains all the sera which failed to hemolyze the cancer corpuscles, but hemolyzed some of the normal or control red cells. Of twenty-five cases falling into this group, eighteen, or 78 per cent. were derived from cases of cancer, while only 33 per cent. of the total number of sera tested came from cancer patients. Taking the cancer serum as a whole, 72 per cent. fall into this group. Of the sera from other diseases only 10 per cent. fall into group 1, and of normal sera 10 per cent. It is, therefore, evident that the type of result designated as group 1, in which a serum hemolyzes one or more of the control corpuscles, but fails to hemolyze any of the cancer corpuscles, is much more commonly found in sera derived from cases of cancer, than from any other condition of disease. The four other sera falling into this group were derived, one from a case of pneumonia, one from a case of sepsis, and two from cases of tuberculosis.

If these percentages be compared with those obtained by Weil in human disease, it will be found that there are certain differences. Group 1, in his cases of malignant tumors, contained 56 per cent. of the cases. The increase in group 1 of the present series is due to the addition of the cases included in group 2 (+ +) in his series, by means of the method of increased dilution of those sera originally falling into group 2. Moreover, group 4 has been diminished to the advantage of group 1, by the use of a larger number of control corpuscle emulsions, thus affording greater likelihood of a positive reaction in one of the controls.

In a large number of these tests, the agglutination of the corpuscles by the sera was also noted. It was not found that the agglutinative and the lytic powers of the sera were to any extent co-ordinated. In fact, they were entirely independent of one another. Furthermore, the resistance of the corpuscles was in each case tested against a graded series of anisotonic solutions of sodium chloride, varying from 0.1 per cent. to 0.8 per cent. Here, also, it was found that the degree of resistance to anisotonic solutions could not be correlated with the degree of resistance to lytic sera. At most, it could be said, as has been previously found (Lang and others) that the corpuscles of cases of advanced cancer are generally more resistant than other corpuscles.

The percentages obtained in the present series do not approach those obtained by Crile, nor is the author able to confirm his statement that cases of tuberculosis may be distinguished from cases of cancer by the presence of a "reverse" reaction. In the absence of detailed data it is impossible to enter into a further analysis of the differences.*

Finally, as regards the diagnostic value of the method, it seems advisable to the author to exercise great caution and reserve. Judging from the small series of cases herein reported, it would seem that a very large proportion of cancer cases fall into group 1, and that a comparatively small proportion of other conditions fall into this group. Such a result, however, seems hardly adequate for clinical purposes. The results are, nevertheless, promising, and it is possible that further application of the method may result in such improvement as to make it of considerable clinical value.

*After this article was written Crile published a later article, giving the details of his technique. It may be pointed out that he uses four control bloods as against only one cancer blood, which artificially triples the probability of obtaining a "positive" reaction. Further, he uses as the unit of dilution the whole blood, instead of the centrifuged corpuscles, which must yield emulsions five times as strong in some cases as in others, depending upon the degree of anemia. Sedimentation of the corpuscles, which he advises in place of centrifugation, has been condemned by as high an authority as Madsen. These errors of technique seem adequate to account for the high percentage of positive reactions which he has obtained.

A NEW APPARATUS FOR INTRATHORACIC OPERATIONS UNDER DIFFERENTIAL PRESSURE.

A PRELIMINARY COMMUNICATION.

By WILLY MEYER, M.D.,

NEW YORK.

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, ATTENDING SURGEON TO THE GERMAN HOSPITAL, CONSULTING SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL AND NEW YORK INFIRMARY.

WHEN Dr. F. Sauerbruch of Marburg, Germany, sailed for home, after last summer's meeting of the American Medical Association, he had the great kindness to leave here for my use the small portable chamber, which he had demonstrated at Chicago and at the Rockefeller Institute in New York.

It is constructed on the general lines of the larger Sauerbruch chambers, but does not have their accessories, without which the features objected to by surgeons using the larger chambers become still more accentuated.

This obtruded itself upon me so strongly, when I began to use the portable chamber, that I determined to improve it.

The first specimen of the improved apparatus has now just been delivered to me. It was designed by and built for me by my brother, an engineer by profession, whom I had the good fortune to interest in the matter. I directed his attention to the neces-

sity of avoiding, above all things, this feature of the Sauerbruch chambers, viz., that the positions occupied by the surgeon and by the narcotizer, when operating under negative pressure, are reversed when positive pressure is employed. Such changing about, I believe, makes the obtaining of perfect asepsis more difficult and uncertain. Therefore I specified that in the improved apparatus it must be possible to perform the operation always in the same spot, irrespective of whether negative or positive pressure be used.

Two types of apparatus were developed: a "universal chamber" for both positive and negative pressure, and a "differential chamber" for positive pressure only.

The "universal chamber" consists of two chambers: a large one—the operating room, and a smaller one—the narcotizing room. A motor-driven air pump ventilates both. Negative and positive pressures are produced by varying the cross section respectively of the air inlet or air outlet pipes by means of valves. The latter are located in the large room at the side of the surgeon, who is thus enabled to call for whatever difference of pressure is required at the moment. He can also change, if he so desires, from negative to positive pressure, or vice versa; or he may have half negative and half positive pressure, or any other intermediate stage, without a change in his own position, that of his patient, or that of the narcotizer and without any interruption of the operation.

The possibility, thus given, to raise at any time the pressure in the larger chamber to atmospheric pressure, while still maintaining the necessary difference of pressure between the two chambers, does away with the necessity of having air-locks for access to the chamber during the operation.

The manipulation of the valves is exceedingly simple and can be readily grasped by the average hospital attendant.

The new apparatus introduces no complication into the operation itself further than that it envelops the narcotizer and the head of the patient, but the narcotizer has free, unimpeded and unencumbered access to the patient's head before him, exactly the same as ordinarily. Through the walls of the chamber, which consist of a skeleton framework and an air-tight covering, he can converse with the surgeon. The latter as well as his assistants have plenty of elbow room.

The head of the patient is adjustably suspended in a headbox which projects out from the narcotizing room, and the bulging rubber collar of old is replaced by guillotine-shutters which do not obstruct the field of operation and are vertically movable with the adjustment of the operating table. A large pane of glass in the headbox exposes the face of the patient to the view of the surgeon and his body to that of the narcotizer. The ventilation is so ample that no condensation of moisture occurs on the glass.

These chambers will cost less than the Sauerbruch chamber, in use abroad. They are of knock-down construction, which adapts them to the requirements of military surgery.

The smaller chamber is what I call the "differential chamber." It can be used independently of the larger one, but for operations under positive pressure only. This is the one which, as I stated above, has just been delivered to me. It is simple; there is nothing in it to get out of order. It is portable; it can be brought to the bedside of the patient, or to the operating table should it be found desirable in the course of an operation to continue the same under differential pressure. I have seen it subjected to and satisfactorily fulfilling the proper mechanical tests, and am now going to try it out surgically in intrathoracic operations on dogs in my work at the Rockefeller Institute for Medical Research.

With the consent of the Board of Directors of the German Hospital of New York, both the differential and the universal chambers, which are now building for me, will find a place in that institution. They are expected to be ready soon for operations on human beings.

New Method of Treating Detached Retina.—In a patient recently exhibited before the Vienna Medical Society, Sachs showed a woman of 49 years who had had several unsuccessful operations for retinal detachment. Sachs then resolved to bring about permanent adhesion of the retina to the sclera at a point where the retina was easily lifted off its base by a collection of fluid. The anatomical conditions were as follows: The retina was fixed to its base only at the papilla and along the ora serrata, nearly in the middle between the margin of the cornea and the æquator bulbi. Then if liquid was accumulating in the subretinal space it would push away the retina easiest in the middle of this distance at the equator. The usual place of puncture was next to the ora serrata or next to the usual place of fixation of the retina; puncture in this situation, however, did not promote fixation in detachment. Sachs, therefore, on the next occasion punctured behind the equator after dividing the conjunctiva and pulling the eyeball a little to the inner side. Twelve days later, as a slight accumulation of fluid appeared again and threatened to break down the adhesions set up by the last puncture, he repeated the operation, puncturing again behind the equator, this time on the inner side after temporarily detaching the rectus internus muscle. The ophthalmoscopic view was very satisfactory; white scars were visible, where the punctures had reached the retina; there was some hemorrhage into the vitreous, but the vision of the patient was excellent and remained so for the six weeks during which she was under observation. After having obtained this good result Sachs operated in the same way behind the equator on three more patients with high myopia and detachment of the retina. An improvement was immediately visible but the time that had elapsed since the operations was insufficient to show whether the result would be permanent or not. No relapse had, however, occurred as yet, although the patients formerly complained that every few days their sight failed them. The method was said to be good for recent cases or for such cases of longer standing as have not yet many folds.—*The Lancet.*

Treatment of Exophthalmic Goiter.—Gilbert Ballet and Louis Delherm tell us that all methods of treatment for exophthalmic goiter have their successes, balanced by their unsuccessful cases. This results from a too narrow conception of the pathogeny of the disease. Some forms of exophthalmic goiter develop from simple goiters or enlargements of the thyroid that are entirely local. In such cases the use of thyroid extract, of iodoform, and thyroidectomy are of value. The syndrome may be caused by affections of neighboring organs; pharyngitis, polypoids in the nasal cavities, etc., and here treatment of these troubles will cause disappearance of the symptoms. Sometimes the disease is dependent on lesions of the ninth sympathetic pair of nerves. Variations in the ovarian secretion and the menopause should be treated as factors in this disease. Whenever we can find a local or reflex cause we may make use of treatment addressed to these causes with success. A large number of these cases cannot be referred to any of these factors. There is simply a hereditary or acquired nervous predisposition, an irritability of the nervous system with a defect of secretion of the thyroid without the possibility of learning which of these factors is the primary one. The first indication is to quiet the nervous system by rest, hydrotherapy, and hygiene. Next to make use of hematotherapy by the use of the serum of animals. Electricity is of value by its calming, vasoconstricting effect and its influence of thyroid secretion.—*La Bulletin Médical.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 9, 1909.

TUBERCLE BACILLI IN A HUMAN OVUM.

BAUMGARTEN is one of the few authoritative workers in tuberculosis who has insisted upon the frequency of transmission of this disease from parents to children. Although the general opinion is that usually only the predisposition to infection is transmitted, yet a number of experimental data have of late been published which show that the possibility of direct transmission of the disease by the ova or the sperm in human beings cannot be denied. Thus Koch and Rabinowitsch have found various stages of tuberculous infection in the genital organs of birds dying of tuberculosis in the Berlin Zoölogical Gardens; later they succeeded in breeding tuberculous chickens from infected eggs and have shown thus that the presence of bacilli does not make the eggs incapable of developing as has been claimed by several workers. That tuberculous infection of the human ovary is not such a rare occurrence as was supposed has been shown by Wolff, who found three cases of such infection among seventeen bodies of persons dead of tuberculosis. These data have led several workers to look for evidence of tuberculous infection of the ovarian follicles in human subjects, and recently Sitzenfrey ("Die Lehre von kongenitalen Tuberculose," Berlin, 1908) has succeeded in finding typical bacilli in the follicles of an ovary removed for tuberculous disease. Of course these findings merely suggest the possibility of direct transmission of the disease by the ova in human beings, the conditions usually found in the tubes in the presence of tuberculosis of the ovaries making it highly improbable that fertilization could take place in such cases. The finding, however, is of interest in connection with the reported presence of *Spirochæta pallida* in large numbers in the ovaries and within the follicles of children dying of congenital syphilis within a few days of birth.

These facts throw a great deal of doubt upon the usual opinion that holds germinal elements as very resistant to infection. Baumgarten freely agreed that the rarity of congenital tuberculosis seemed to disprove of any importance of transmission of the infection by the germ or the sperm elements; however, he claimed that the actively growing tissues of the developing fetus may inhibit the growth of tubercle bacilli which may remain inactive for some period of time after the birth of the child. As soon, however, as this growth becomes less rapid or any favorable conditions affecting the resistance of the tissues appear, tuberculosis develops in these children, who are really the victims of latent infection from birth. Placental infection is, of course, the more usual course of transmission of tubercle bacilli from the mother to the fetus, infection of the placenta being not at all a rare event. Sitzenfrey's finding on the other hand must remain merely of pathological interest when all the circumstances attending the fertilization and development of the human ovum are considered. To decide whether an infected ovum can progress at all in development should be easy when we remember how frequently abortion is induced in tuberculous women because of advanced disease; careful examination of young ova obtained in such cases may give an idea of the relative frequency of direct transmission of infection by the germinal elements.

TRYPSIN IN THE TREATMENT OF SURGICAL TUBERCULOSIS.

THE experiments of Jochmann and Müller have shown that the introduction of ferments derived from polynuclear leucocytes into tuberculous abscesses leads to rapid resorption of the contents of these lesions; their explanation of this curative action is founded upon the proteolytic action of the leucocyte ferment which quickly changes the pus in the abscess into a form that can easily be absorbed. The presence in tuberculous lesions of lymphocytes that are poor in ferments to the exclusion of other leucocyte forms explains the chronicity of the processes of this character. Lately Jochmann has determined that the proteolytic action of leucocyte ferment could be easily produced by solutions of trypsin, and in the *Münchener medizinische Wochenschrift* for December 1, 1908, he and Baetzner report the success that the method met in practical application. The authors used a solution of 1 gm. of trypsin in 100 c.c. of sterile salt solution, injecting one to two cubic centimeters of this fluid at a time. The solution was introduced directly into the foci of disease, this procedure being only moderately painful. The contents of tuberculous abscesses very rapidly became serous in character and disappeared by resorption; at the same time the granulation tissue of the abscess walls seemed to be stimulated by the presence of the ferment and soon filled out the cavity of the abscess. Equally favorable results were obtained with the treatment of tuberculous fistulæ or sinuses as well as of tuberculous lesions of the skin.

Curiously enough the opposite procedure, that is, the introduction of substances rich in antiferments, seemed to have a very good action in causing more rapid healing of acute suppurative processes. The excess of ferment carried into such lesions by the polynuclear leucocytes seems to inhibit proper reparative response of the surrounding tissue, and the use of tampons soaked in hydrocele fluid, which has an antiferment power, led to the rapid victory of the processes of repair over the destructive action of the infecting agent. The results simply further corroborate the truth of the assumption that the phenomena of inflammation, while reparative

in quality, may prove harmful because of their quantitative excess over the needs of the local tissues in the struggle against injury.

Sea-Water Injections.

A new method of treatment of chronic diseases that has been much used recently in France is the injection of sea-water into the muscles. The use of sea-water in this way is founded upon the researches of Quinton, who found that the chemical composition of sea-water and that of the vital plasma are almost exactly the same. All cells react energetically to changes in the medium in which they exist; to produce better function we must remove intoxication products, and return the blood plasma to its original composition. G. le Mehauté, in a brochure entitled "l'Eau de mer en injections hypertoniques dans le traitement des maladies chroniques" (Maloine, Paris, 1908), explains the best method of availing ourselves of the active qualities of sea-water. There are two ways of using it: It may be diluted to make isotonic marine serum, which is injected in large amounts, or it may be used in its natural state as hypertonic marine serum, the latter being given in very small intramuscular injections. The disadvantages of the isotonic serum are that its injection raises the blood pressure, on account of the large amount that must be injected, and thus it cannot be used in cases in which there is weakness of the arteries from arteriosclerosis or other vascular disease. The small injections, on the other hand, are very well borne and have a marked tonic effect on the organism; they do not increase the volume of the blood and are absolutely harmless. This plasma may be rendered more active and valuable by the addition of other medicaments, such as mercury, phosphorus, or arsenic, during its preparation. The sea-water is obtained in sterile containers, from considerable depths of the sea, and at a distance from land. In the laboratory it is sterilized and is placed in small tubes, which are so made that a hypodermic needle can be attached at one end and a rubber bulb for expelling the fluid at the other. The dose is five cubic centimeters at each injection, and it can be repeated daily when thought best. When used for syphilitic treatment a course of two months' injections is interrupted for one month and then repeated. All the unpleasant effects of mercury are said to be thereby prevented and the treatment is rapidly effective. The phosphated plasma is asserted to be of great value in nervous diseases and in cases of acute mania. Arseniated plasma is used for the treatment of dyscrasias, and iodized plasma for scleroses. The intramuscular injections are painless and cause no soreness at all. Mercurial plasma is more active than calomel or gray oil. The preparation of these various "marine sera" seems at present to be confined to France, but if the method becomes popularized here in response to the missionary efforts now being made, it would hardly be necessary to cross the ocean to get sea-water. The Council on Pharmacy and Chemistry might be persuaded to endorse the home product, even if it was not "made in Germany" or in France.

Dr. Wiley Should Be Retained.

It is to be hoped that the rumors from Washington to the effect that Dr. Wiley, Chief of the Bureau of Chemistry of the Department of Agriculture, is about to retire are untrue, for the country could ill afford to lose his services at this time. He has, unfortunately, made many enemies, more than there was any necessity of making, and these enemies are bringing every possible influence to bear upon his superiors to force his resignation, or at least to limit his authority. In his fight for pure food and pure drink it was inevitable that he should antagonize powerful interests, not only the dishonest manufacturers and wilful adulterators, but many also who used preservatives believing them harmless. Among the latter are men of integrity, who would be ready and willing to change their methods if they could be convinced that they were wrong, but who are naturally averse to being coerced by the big stick unsupported by sound argument. In the discussion of the use of preservatives, Dr. Wiley's conclusions have at times been hasty, and the "poison-squad" experiments upon which these conclusions were based were somewhat lacking in scientific accuracy. This is particularly unfortunate, since it is on the results of these experiments that the argument is based, and where the financial interests affected are so great, none but the most convincing evidence can overcome them. If the benzoates, the sulphites, formaldehyde, and other preservatives are injurious in the quantities used, they should, of course, be forbidden, and in any case the users of foods containing them should know what they are getting; but the mere assertion that they are harmful when taken occasionally in minute quantities, is not sufficient, and Dr. Wiley has been unwise in insisting on prohibition before he has proved his case. But this is only a small part of the pure food crusade, and the immense good that Dr. Wiley has done and is doing should not be nullified by his mistaken zeal in one direction. The country is under a debt of gratitude to him for what he has accomplished, and it would be nothing short of a calamity were his services to be lost merely because he occasionally falls short of perfection.

News of the Week.

The Harvey Society.—The seventh lecture of the Harvey Society will be delivered on Saturday evening, January 9, at 8:30 o'clock, at the Academy of Medicine, New York, by Professor J. B. Leathes of the Lister Institute of Preventive Medicine, on the subject of "The Relation of the Liver to the Metabolism of Fat."

Condemn Antivivisection.—At the sixtieth annual convention of the American Association for the Advancement of Science, held at Johns Hopkins University during the week commencing December 28, the governing council adopted the following resolution, which is regarded as an excellent and comprehensive treatment of the subject:

From time to time, attempts, fostered largely by erroneous statements and accusations and false sentiment and prejudice, are made in some parts of the country to enact specific legislation, prescribing the conditions under which experiments on animals may or may not be performed.

Be it resolved by the Association for the Advancement of Science that animal experimentation has been of incalculable benefit to medical science and art, the progress of which is absolutely dependent on experimental methods, as are all the physical and natural sciences.

That no abuse of the practice of animal experimentation in the country has been shown to exist to warrant specific legislation relating to the general subject of prevention of cruelty to animals.

That the unrestricted performance by proper persons of scientific experiments on living animals is essential to the maintenance and progress of medicine and biology.

Vital Statistics of New York City.—For the week ending December 26 the death rate in the city was only 15.07 per thousand of population, the total number of deaths being 1,278. For the same week last year the total number was 1,691, and the rate 20.59. There was a decrease of almost 200 deaths in tenement houses. But two deaths were caused by influenza, which last year caused sixty-three deaths during the same time. For the year ending December 31, the death rate is the lowest on record. The rate has in fact been steadily decreasing for the last five years. The total number of deaths for 1908 was 73,171, that is, a rate of 16.52 per thousand, the lowest rate in the history of the city, and one of the lowest city records in the world. Deaths from several diseases were considerably below the average of the last five years. Some of the decreases are: Typhoid fever, 197; malarial fever, 42; smallpox, 7; whooping cough, 184; diphtheria and croup, 317; influenza, 77; phthisis, 573; spinal meningitis, 778; apoplexy, 1,116; acute bronchitis, 735; pneumonia, 2,823, and bronchial pneumonia, 149. The Health Department takes much pride in a decrease of 3,015 in the number of deaths among children under five years of age. The total decrease from the average of the past five years was 9,249. Only three diseases showed an increase. These were measles, 39; scarlet fever, 599; and cancer, 76. There were also more suicides, though the number of deaths from accidents was diminished. The total number of births for the year was 126,863, a rate of 28.68 per thousand, the highest in the city's history. The birthrate in New York has shown a steady increase for the past ten years.

Vital Statistics of Philadelphia.—The death-rate of Philadelphia for the year 1908 was the lowest in the history of the city, being 17.16 per thousand of the population, as compared with 26.10 in 1864, 26.19 in 1872, and 18.30 in 1907. There was a total of 26,304 deaths for the year, as against 27,462 in 1907, in the face of an increase in population. The improved results are ascribed to the adoption of better precautions against the spread of preventable diseases.

A Record-Breaking Exhibit.—An attendance of 350,000 in three weeks at the International Tuberculosis Exhibit of the Charity Organization Society, an exhibit which can scarcely be considered cheerful except to a person who sees progress in the treatment of the disease, is the record-breaking figure reached on December 21 in New York. Before the exhibition is closed it will probably have been viewed by half a million of people. This large attendance, however, has added to the expense beyond the original estimates, and an earnest appeal has been made for $16,000, in order that the exhibit may remain open until the middle of January. When the exhibit closes in New York, it is to be taken almost in its entirety to Philadelphia, where great preparations are being made to house it and to display it properly. Meanwhile, a most cordial invitation is extended to all interested in the prevention of tuberculosis to visit the exhibit in New York.

Vaccination: What It Is.—Under this title the New York State Department of Health has issued a pamphlet compiled by Dr. F. C. Curtis, consulting dermatologist to the department. Beginning with a history of smallpox, the pamphlet describes Jenner's discovery of the protective influence of vaccination and uses many striking photographs to illustrate this and the technique and care of vaccination. Attention is paid especially to the mild form of smallpox, which has for some years past been prevalent in the State, but which retains many of the characteristics of the more virulent type, and can be successfully met only by compulsory vaccination.

To Aid Medical Inspectors.—The Chicago Medical Society, through its Council, has inaugurated a movement to procure increased compensation for the public school medical inspectors. The Council's special committee has been at work for several months investigating the question of contract practice, with special reference to the doctors in the employ of the Health Department. This committee has reported that the salary of $50.00 a month received by each inspector is inadequate, and recommended the adoption of resolutions fixing a certain stipend to be paid to school doctors.

Pasadena Reports Infectious Diseases.—The Mayor and Council of Pasadena, Cal., have recently passed a resolution favoring a more rigid enforcement of the ordinance compelling the reporting of all infectious diseases, including tuberculosis, and have also made provision whereby the fumigation of all rooms and houses vacated by any infectious or tuberculous case shall at once be thoroughly disinfected by a city official at the city's expense. The Pasadena Medical Society is giving the Health Officer its unanimous support in the carrying out of the ordinance, and the women's clubs and real estate firms are also enthusiastic supporters of the movement.

Clean Cars.—Speaking at the Tuberculosis Exhibit on January 2, Mr. Frank H. Hedley, Vice-president of the Interborough Company, described the precautions taken by the company to keep the cars in a sanitary condition. He said that the thick matting which was at one time used in the cars had been done away with because it was recognized that the matting was a catchall for disease germs. The matting, Mr. Hedley said, had been replaced by hard maple strips three-quarters of an inch square and the same distance apart. Every night the floor of every one of the 2,500 subway and elevated cars is sprinkled with a five per cent. solution of carbolic acid. The floors are then swept clean, and after the dust is settled it is wiped up carefully with cheesecloth instead of being churned up with feather dusters. Every week, and oftener if necessary, the floors are scrubbed with a soft soap containing so strong a solution of alkali that it will remove the paint wherever it is allowed to come in contact with it. Every month the interior of each subway car is cleaned with an oil emulsion, which gathers up all of the fine particles of dust, and every year at least every car is painted, varnished, and oiled. Every night the straps are cleaned with an acid solution which will kill any germ.

Report of the Cook County Board.—The report from the Cook County (Ill.) Board gives prominence to several features, among which are the overcrowded conditions at the Dunning Institutions, preparation for the construction of the new

County Infirmary, and the beginning of the work on the new consumptive hospital.

To Investigate Occupational Diseases.—Dr. James W. Pettit of Ottawa and Dr. James A. Egan of Springfield, Ill., have been appointed by Governor Deneen as members of the States Commission to investigate occupational diseases.

Memorial Hospital.—The Delgado Memorial Charity Hospital, built as a memorial to Samuel and Virginia Delgado and presented to New Orleans by their nephew, was dedicated on December 19 with appropriate exercises. Addresses were made by the Governor of Louisiana, the Mayor of New Orleans, Dr. Matas, and others. The five-story building is strictly fireproof and thoroughly up to date in its equipment.

Report of Morris Plains State Hospital.—Dr. Britton D. Evans, in his annual report of the New Jersey State Hospital at Morris Plains, says that in the last thirty-two years 8,953 patients were admitted to the asylum, of whom 2,173 were discharged as cured, a percentage of about 24. During the last year, 26 per cent. of those admitted have been discharged as cured; and of the remainder 22 per cent. showed hereditary taints. A singular fact is that of the patients admitted last year 30 per cent. were housemaids. Dr. Evans is firm in his assertion that convicts should be kept out of such institutions, and says that the presence of seventy-one convicts in the hospital is a disgrace to the State.

Roosevelt Withdraws Its Ambulances.—Dr. James W. McLane, President of the Board of Trustees of the Roosevelt Hospital, New York, has announced that at a recent meeting of the Board it was decided to discontinue the ambulance service, probably on March 1. The trustees say that while they are perfectly willing to treat all cases brought to them, they consider that the city should support the ambulances, which service is distinctly a police duty. The hospital ambulances have covered the district from Twenty-seventh street to Eighty-sixth street, and from the Hudson River to Seventh and Eighth avenues. This action will be beneficial in calling attention to the recommendations for the establishment of emergency hospitals for accident cases already made by the State Charities Aid Association and by the Mayor's Hospital Commission, and in making some action by the city authorities imperative. As at present managed the ambulance service is entirely without system; and there can be no question that the burden of maintaining a properly organized service should rest upon the city and not upon the hospitals.

The Modern Woodmen's Sanatorium.—The Modern Woodmen of America have recently acquired some 1,300 acres of land near Colorado Springs, upon which they are establishing a sanatorium for the treatment of tuberculosis, the tent colony plan being employed. The first colony was opened the first of the year, and is equipped to care for sixty patients. A second colony will probably be opened about July, 1909. Members of the Society suffering from tuberculosis will be treated free of charge, as it is estimated that each life saved to the Society by this sanatorium will represent a saving of $1,700, at an expense for treatment of approximately one-twentieth of that sum. The plan is commended to fraternal organizations and life insurance companies generally.

Fire in Sydenham Hospital.—More than a score of women patients and as many babies were hurriedly removed from the maternity ward of the Sydenham Hospital in New York on the morning of December 24, because of a fire which started in a Christmas tree in the nurses' dining-room over the ward. The patients were carried into other parts of the hospital, and the work of removal and of fighting the fire was carried out so quietly that but few of the other patients knew of the blaze. The damage amounted to less than $300.

Chicago Pasteurizes Milk.—Beginning on January 1, Chicago put into effect an ordinance requiring the pasteurization of all milk except such as comes from cows which have been proved to be free from tuberculosis by the tuberculin test. The new ordinance was the result of a serious epidemic of scarlet fever in the city not long ago, when it was decided to resort to pasteurization both to prevent the recurrence of such outbreaks and to stop the spread of tuberculosis by the use of raw milk.

Annual Report of the Cook County Hospital.—During the fiscal year 1908, 28,142 patients were admitted to the County Hospital, Chicago. At the beginning of the year there were 1,145 patients there, and at the close, 1,322. The daily average number of patients in the hospital during the year was 1,274. The average cost for the care of each patient for one day in the County Hospital and the Detention Hospital, which are provided for in one appropriation, is 99 cents.

Charitable Gifts.—The Union Hospital of Fall River, Mass., has received a gift of $50,000 from Mrs. E. E. Stevens, and from the estate of the late Miss Elizabeth M. Borden a fund of $10,000 for the endowment of free beds for crippled children. Mr. Isaac Guggenheim of New York has offered to contribute to the funds of the Sydenham Hospital an amount equal to that contributed by all other subscribers during the year 1909. The expenses of this hospital have been largely increased through the purchase of four adjacent buildings as an addition to the present quarters. By the will of the late George M. Laughlin of Pittsburg, the Pittsburg Hospital for Children receives $25,000; the Southside Hospital for Children, $25,000; the Mercy Hospital, $25,000; the Protestant Home for Incurables, $25,000; and the Memorial Home for Crippled Children, $25,000.

Red Cross and San Francisco.—The Relief and Red Cross Society, which at the time of the earthquake and fire in San Francisco received donations amounting to nine and a half million dollars for distribution among the sufferers, has made a final report of its receipts and disbursements. The report shows a balance on hand of $397,267, which it had been planned to turn over to hospitals and charitable institutions in the city. It is now probable, however, that a part of this will be sent to the earthquake sufferers in Italy. The actual cost of distributing the nine and a half millions was only 2.03 per cent. of the entire sum disbursed. Much of the work done is of a permanent character. For instance, the society provided or assisted in providing for about 8,000 homes in San Francisco, at a cost of about $1,900,000. The Relief Home for the Aged and Infirm was also built and presented to the city. Besides these, large contributions made to hospitals and other charitable institutions have materially aided in their rehabilitation.

International Medical Congress.—Arrangements have been perfected for the American party which will attend the International Medical Congress at Budapest in August. Transportation arrangements are in the hands of Thomas Cook and Son, and rooms have been reserved at some of the best hotels in the city, but it is necessary for the committee to know at an early date approximately the number expecting to attend. All communications in regard to membership or scientific program should be addressed to Dr. J. H. Musser, Chairman of the American Committee, Philadelphia, while communications in regard to transportation and hotel accommodations should be addressed to Dr. Charles Wood Fassett, St. Joseph, Mo.

The Connecticut Society for Mental Hygiene.—At a meeting of the Board of Directors of this Society held in New Haven on December 11, the following officers were elected: *President,* George P. McLean; *Vice-Presidents,* R. H. Chittenden and J. H. Whittemore; *Treasurer,* Thomas Hooker. This Society, which it is hoped may be the forerunner of a National Association for Mental Hygiene, plans to accomplish in the field of nervous and mental disorders results comparable to those already accomplished in the fight against tuberculosis. The Connecticut Society is the first of its kind to be organized in this country for the work of attacking insanity along preventive lines.

The Eighth District of the South Dakota State Medical Society met in Yankton on December 17. The following officers were elected: *President,* Dr. S. M. Hohf, Yankton; *Vice-President,* Dr. J. L. Stewart, Irene; *Secretary-Treasurer,* Dr. F. L. Beal, Irene.

The Jefferson County (Ala.) Medical Society held its annual meeting at Birmingham on December 21, at which the following officers were elected: *President,* Dr. J. D. Heacock; *Vice-President,* Z. B. Chamblee; *Secretary-Treasurer,* Dr. A. F. Toole.

The Fall River (Mass.) Medical Society at its annual meeting on December 24 elected the following officers for the ensuing year: *President,* Dr. John Westall; *Vice-President,* Dr. J. A. Abbe; *Secretary,* Dr. J. E. Huard; *Treasurer,* Dr. D. R. Ryder; *Librarian,* Dr. G. L. Richards.

The Santa Clara County (Cal.) Medical Society at its annual meeting on December 16 elected the following officers for the ensuing year: *President,* Dr. William Simpson; *Vice-Presidents,* Dr. H. C. Brown, Dr. W. F. Snow, Dr. J. W. Thayer; *Secretary,* Dr. J. W. Kocher; *Treasurer,* Dr. H. J. B. Wright. In accordance with the by-laws of the Society, Dr. J. L. Asay, who has been a member of the medical profession for fifty years, was elected an honorary member for life.

The Knox County (Tenn.) Medical Society held its annual meeting on December 17 at Knoxville. The following officers were elected: *President,* Dr. S. D. Acuff; *Vice-President,* Dr. J. P. Tillery; *Secretary,* Dr. S. H. Hodge; *Treasurer,* Dr. C. W. Rain.

The Allen County (Kan.) Medical Society at its annual meeting on December 16 elected the following officers: *President,* Dr. C. J. Halm; *Vice-President,* Dr. R. O. Christian; *Secretary,* Dr. O. L. Cox; *Treasurer,* Dr. F. H. Martin; *Censor,* Dr. G. W. Moore.

The Faulkner County (Ark.) Medical Society held its annual meeting on December 17. The election of officers resulted as follows: *President,* Dr. G. L. Henderson; *Vice-President,* Dr. W. R. Greeson; *Secretary-Treasurer,* Dr. I. N. McCollum.

The Pacific Slope Health Association, at a meeting in Portland, Ore., on December 15, elected the following officers: *President,* Dr. N. K. Foster of Sacramento; *Vice-President,* Dr. R. C. Yenney of Portland; *Secretary,* Dr. E. E. Heg of Seattle. The meeting was called for the purpose of perfecting organization for a vigorous campaign to stamp out bubonic plague through the enforcement of strict quarantine at all customs ports of the Pacific Coast. The association adopted resolutions recognizing the value of the work already done in stamping out the disease among men and reducing it to a minimum among rodents, but asserting that the necessity for continuing the work for an indefinite period still exists, and that this work should include the extermination of rodents. The association further recommended the disinfection of all vessels at least once a month, the instituting of such sanitary improvements as will secure efficient collection, care, and destruction of garbage and stable offal, and the rendering of all buildings, docks, warehouses, markets, etc., rat-proof.

Dr. Archibald Church has resigned the editorship of the *Chicago Medical Recorder.* This journal was formerly the organ of the Chicago Medical Society, but latterly has been free from all entangling alliances.

Dr. Walter S. Reynolds of this city has been appointed Professor of Venereal Diseases in the Medical Department of Vermont University, Burlington, Vt.

Memorial to Dr. McCosh.—Active work has been begun to erect a memorial at the Presbyterian Hospital to the late Dr. Andrew J. McCosh, to take the form of a building for surgical cases in connection with the hospital. An appeal for funds has been made by a committee, of which Mr. John S. Kennedy is chairman. "We ask," says the letter, "contributions from those who were fortunate enough to have felt the skilled hand, as well as those who knew the generous, loving heart of the friend as well as the physician."

Obituary Notes. Dr. Samuel Hart of Marietta, Ohio, died at his home on December 20, after an illness of nine months. Dr. Hart was born in 1830, and studied medicine in his father's office in Marietta, until the outbreak of the Civil War, when he was commissioned surgeon and assigned to duty with the 63d Ohio Volunteer Infantry. At the close of the war he spent a year in study at Bellevue Hospital, New York. He was a member of the American Medical Association, the Ohio State Medical Society, and the Washington County and Marietta City Medical Societies.

Dr. Alice Boole Campbell of Brooklyn, N. Y., died on December 31, after several months' illness from angina pectoris. Dr. Campbell was graduated from the New York Homeopathic College and Hospital for Women in 1867, and was one of the founders of the Eastern District Homeopathic Hospital and Dispensary and of the Women's Memorial Hospital. She was the first woman to gain admission to the Kings County Medical Society.

Dr. Alfred Russell Goodrich of Vernon, Conn., died at his home on December 28, aged 92 years. Dr. Goodrich, who was the oldest physician in the county, was graduated from the Berkshire Medical College in 1846. He was at one time Secretary of State and State Controller of Connecticut.

Correspondence.

CLIMATIC TREATMENT OF NEPHRITIS.

To the Editor of the Medical Record:

Sir:—In an article published in the *Deutsche medizinische Wochenschrift*, No. 48, 1908, by Prof. H. Strauss of Berlin, dealing with "Climate and Kidney Diseases," the author approves of climatic cure only: (1) for the convalescence of acute affections; (2) for subacute or chronic diffuse nephritis; (3) for orthotic albuminuria, and (4) for chronic diseases of the urinary passages; whereas he disapproves of it for acute processes and for such phases and complications of kidney diseases which confine the patient to bed or which at least render him unable to be transported. He praises Egypt as an ideal winter resort, not only on account of the long continued irradiation of the sun and the dryness of the air in the desert, but also on account of the peculiar feature of the current of air which render high temperatures less disagreeable and oppressive. Thus the patient is enabled to enjoy the fresh air all day long the whole winter through and at the same time to evaporate through his lungs and skin much water, and with it a great deal of the products of final metabolism.*

As recent investigations have shown a parallelism in the vascular reaction of both skin and kidneys, there is room for the supposition that the solar rays cause an active cutaneous as well as renal hyperemia. But not to omit the one dark point in the bright picture, there is danger of taking cold in the sudden fall of temperature at sunrise and sunset, because of which a change of latitude is recommended, namely, Helouan for fall and spring, Assouan for January and February, and, if possible, Luxor for December and March. Whereas full recovery occurs only in a small percentage of cases of chronic parenchymatous nephritis, decided improvement is to be hoped for in nearly every case.

As I had the opportunity to observe and treat one of the first mentioned cases, I wish to call the attention of my confrères to the curative climate of Egypt which seems not to be so widely known as it deserves. In fact, at the time, I found there many Englishmen, but not one American suffering from nephritis.

My patient was a young man of 24, of athletic build, second lieutenant of cavalry, who contracted, by taking cold or by high living or by both, a parenchymatous nephritis a year or more before I saw him. At that time he was treated in a hospital by the first authorities for some months and suffered considerably from weakness, headache, vertigo, nausea, and anasarca. When the latter symptom had disappeared, in November, the patient was advised to go to Egypt for the winter, and as he was too weak and too sick to travel alone, I became his companion and physician. On the way to our destination from the center of Germany by railroad and steamer, all the mentioned symptoms did not leave him, but were even aggravated by a short sea sickness. Arrived in Africa we hurried from Alexandria to Cairo and then undertook a voyage on the Nile in a dahabiyeh (private sailing vessel). From that time on, I noted a daily improvement in his health and a decrease of the albumin and the granular and hyaline casts and other findings in his urine. When we arrived at Wadi-Halfa, the southernmost point of our trip, a month and a half after our departure from Cairo, his urine and his health were entirely normal, although he did not abstain from alcoholic beverages and, due to the hunger peculiar to this climate, ate quantities of meat.

In sailing north again a slight recurrence of albumin and casts was to be noticed, but disappeared after about two to three weeks. Returning to Cairo, just three months after setting out, he was as strong as before his illness. The completeness of his cure was demonstrated by the fact that a freshly acquired gonorrhea with epididymitis did not bring on a relapse of the nephritis, and healed in about six weeks during our stay at the sulphur-bath of Helouan. After crossing the Mediterranean in May we traveled slowly northward through Italy during five weeks and returned to Germany in June.

That the cure was a permanent one, I ascertained by occasionally visiting him during the last thirty-four years, always finding him in good health and his urine without any abnormity in spite of his good living and hard work on his large country estate.

Oswald Joerg, M. D.

12 Schermerhorn Street, Brooklyn, N. Y.

*He calculates the loss of liquid through perspiration in the desert climate 2½ to 3 liters (about 2½ to 3 quarts), and with this 2½ to 3 grams (38 to 45 grains) of nitrogen.

THE OPIUM HABITUE AND THE ORDINARY MAN.

To the Editor of the Medical Record:

Sir:—Though a clergyman, and not a practising physician, I read with interest Dr. Waugh's paper on "The Opiate Habit" in your issue of December 26. I was surprised at the eighth paragraph in that paper, in which occur the following words: "Some settle down to a certain dose and adhere to it for years; others devote their lives to the effort of absorbing all the opiate they can crowd into their systems. The life of the former runs on uneventfully. They live, perform a certain limited series of mental and physical evolutions, but their progress ceases. Their career culminates. They gradually retire from the activities of the community and grow yearly more contracted in their operations and their sympathies. Ambition is dead, incentive has perished—they just live and no more. The man collects his little rents, sees to his little kitchen garden, eats a trifle, wears his old clothes and sits alone at home reading a bit, meditating long, ruminating most of the time; producing nothing; a quiet, inoffensive, retiring hermit, of no use to himself or to anybody else, neither hated nor loved by any mortal man. Only the druggist knows the truth."

To my mind that is a strange description of the man who has acquired the opium habit. Is it not rather an excellent description of the average good citizen in any village or small city? How much ambition have most men of restricted means and limited education, who have seen little of the world, and are over sixty years of age? What could Dr. Waugh expect such men to produce? I should think the less they produced the better it would be for them and for others. Dr. Waugh seems to think "producing" is the great end of human life. Thousands of very good men produce little or nothing, and yet they are in their way of service to the human family. The consumer, if he pays well for what he consumes, is a very desirable member of the community in which he lives. Is the quiet and inoffensive life of the man producing little or nothing, who spends his time with books, and is a "retiring hermit," but a burden to no one, good evidence of the presence in the community of an "opium fiend"? I should be very sorry to think that such a life as has been described bears any close relation to the habitual use of opium.

I have known some eaters of opium who were very different men from those described in the paragraph under review. They were not humdrum, commonplace men, but men of unusual mental activity. In the end extravagant use of the dangerous drug destroys a very considerable per cent of them, but they were, none of them, such men as Dr. Waugh brings before us. I was personally acquainted with Capt. Frederick Lahrbush, who lived to be more than a hundred years old, and I thought that his length of days was in some measure due to the tranquility of more than half of his life, an absence of irritability, and a contented disposition. I have seen him drink at one time more laudanum than would kill ten men unused to the drug. There was a very correct picture of him when he was supposed to be one hundred and nine years old in an article on "The Curiosities of Longevity" in *Scribner's Monthly* for November, 1875. Surely Coleridge, De Quincey, Erskine, Dr. Hall, Kimball, John Randolph, Wilberforce, and the poet and artist Rossetti were not dull and stupid men whose lives were uneventful, whose ambition was dead, who produced nothing, and who were mainly of interest to the druggist. Not one of the persons named lived a stupid life. Not one of them confined his attention to "little rents" and "the kitchen garden." Not one of them died young.

I do not wish to be understood as approving an evil habit or as desiring to blunt the force of Dr. Waugh's attack upon wrongdoing. The warning he sounds is timely, but surely his description is inaccurate, and does injustice to a class of men who consume and do not produce, who live with their books, who are quiet and inoffensive hermits, but who do *not* use opium and should not be exposed to the suspicion of so doing.

KING EDWARD'S HOSPITAL FUND—THE SUNDAY FUND, INTERRUPTION OF MEETING—MEDICAL PROVISION FOR SCHOOL CHILDREN—REMOVAL OF THYROID—STRANGE DEATHS ON A STEAMER—OBITUARY.

LONDON, December 18, 1908.

On Monday the grants of the King's Hospital Fund recommended by the committees were awarded at a meeting under the presidency of the Prince of Wales. The reports of the Distribution and Convalescent Homes Committees were adopted on the motion of the Prince President. They were elaborate statements, and touched on several points in hospital management. As the Prince's speech included most of these, and was very full and explicit, it will suffice to give an abstract of it. He hoped the reports would be satisfactory to all. The donations for the year included Lord Mount Stephen's munificent gifts of £100,000 and Lord Iveagh's of £10,000, both of which have been placed to capital account. One hundred and forty thousand pounds sterling was allocated for distribution among hospitals, convalescent homes, and country sanatoria, being £19,000 above last year's sum. King's College Hospital has another £5,000, making a total amount of £27,000, and the new building has begun "in a district," said the President, "where it has long been needed." The London Hospital is granted £12,000, including £2,000 toward reduction of debt. The fund adheres to the policy of aiding the extension of hospitals situated in the poorer districts remote from the larger general hospitals, and His Royal Highness expressed satisfaction that the committee had given such careful attention to a survey of the metropolis as to the abundance or scarcity of accommodation in different districts, and their report afforded enlightenment and guidance in forming a judgment on the question of unoccupied beds. He also held that convalescent homes, which complete the cures begun in the London hospitals, were in numerous cases essential and acknowledged the indebtedness to the Parochial Charities for their help in this matter. It was decided at last year's meeting to extend the operations of the Fund to consumption sanatoria in the country which received patients from London, but only a small number had applied so far. One step in this direction which the President thought deserved support and encouragement was the National Association of Sanatoria for Consumptive Workers established by workers themselves, Beninden Sanatorium being the first outcome of this movement. Though subscriptions had not increased so fast as was hoped, the President said those of the League of Mercy, to which he expressed his thanks, had steadily advanced. Sixty-six hospitals this year share in the distribution, and for the first time expenditure on in-and-out-patients has been separated. There was reason to hope that the new system of accounts would further assist in the control of expenditure. Over 100 members served as visitors or on committees, a fact which the president thought was a guarantee to subscribers and the public that the fund was well distributed. The plan adopted last year of not nominating any individual to more than one committee had been so satisfactory that it would be continued. To the honorary officials of the fund, as well as to those of the League of Mercy, the president offered his warmest thanks for their devoted, untiring, and most valued services. The arrangements for next year were considered and approved and other formal business disposed of. The president was accorded a hearty vote of thanks for the earnest way he had taken up the rather heavy work for the poor of London. In reply he mentioned that the King was pleased with the progress made and charged him to congratulate the Council on its management.

The League of Mercy has made grants, with the sanction of the Prince of Wales, to extra-Metropolitan hospitals amounting to £1,516 for the year now closing.

The Sunday Fund's meeting was held on Wednesday. The Lord Mayor opened the proceedings by expressing his gratification that the record sum of £80,000 had been received, though the sum collected in places of worship was £2,500 less than last year. The report recommended grants to 164 hospitals and institutions, 60 dispensaries and 29 nursing associations. On its being moved and seconded, an unusual division occurred. The Vicar of St. Mark's, Whitechapel, rose to move an amendment to protest that no grant had been allotted to the "anti-vivisection hospital." Considerable interruption and laughter followed, and the Lord Mayor ruled that the question was not for that meeting but for the Council. But the Vicar declared contributing congregations had a right to a voice, and he and another had been deputed at a vestry meeting to come and protest. Much confusion arose, amid which the Lord Mayor told the Vicar he had not brought the matter before the Council and it could not be discussed. The reverend gentleman still persisted amid constant interruption and cries of "Chair!" and "Sit down!" The Lord Mayor firmly held to his ruling that the amendment was out of order. The Vicar of St. Peter's, Brockley, then pointed out that the clergyman who was so enthusiastic for hospitals had a congregation which had contributed to the Fund the sum of 3 shillings and 3 pence. When the laughter and cries of shame had subsided Sir John Bell said he thought it a shame, indeed, that a clergyman whose congregation gave such a sum should come to interrupt the proceedings. He considered the reverend gentleman was not there in the interests of either hospitals or the public. This opinion was endorsed by the meeting's loud cheers, and the interruptor declared it was "a shame he should be bullied." The report was carried with three dissentients, other business was completed and next year's Hospital Sunday fixed for June 13.

The London County Council has taken up the subject of school clinics, and yesterday the debate came on respecting the reports of the majority and minority of the special subcommittee appointed in July, 1907. They bring out with clearness facts with which medical men are quite familiar, but which many of the newspapers pronounce shocking, although in a different guise these facts have often been brought to their notice. Numbers of children in the elementary schools are not only weakly, but suffering from disease—not a few the result of neglect. We are assured that 90 per cent. at one school were in need of dental treatment—a fact which might be parallelled in other classes, if a dentist inspected all the children in his neighborhood. The Council's medical officer reports that "12 schools taken at random in various parts of London lost 26,766 attendances from ringworm in 12 months." Further, we are told that a large number of scholars suffer from "general debility" and are therefore "prone to fall victims to zymotic diseases, and particularly tuberculosis." The specialists in education are urging that these facts prove the necessity of taking up the matter in order to help the children profit by their lessons. On one side it was proposed to establish school clinics under the control of the Council by their own medical officers. The minority report recommended that arrangements be made with existing hospitals and dispensaries, which are to be paid for the work out of the rates. To neither of these parties did it occur that there is in every locality a number of general practitioners who could do the work and would be glad to undertake it on very moderate terms. The discussion yesterday brought out sharp differences and ended in the adoption of the minority report—not without a vigorous effort on the part of the Socialists to go further.

One Councillor said dispensaries were only shops for the sale of dark colored stuff with a taste of peppermint, and in this twentieth century we had ceased to believe in medicine. If poor law infirmaries were utilized the "children would be pauperized." He did not seem to see that this "stigma of pauperism" was a mere pretence when the children were being fed out of the rates. Another speaker said they could not put pressure on the parents to join dispensaries. He could not see that they might bring to the notice of a parent that his child ought to go to his private doctor and put pressure on any one who neglected to do so. The poorer ratepayers are pressed enough by the "educationalists" and are being driven into the ranks of the Socialists, who promise to feed, clothe, and otherwise provide for their children, and so repudiate parental responsibility. This is diminishing the subscriptions of those better off, as the Mayor of Westminster recently stated, and added that for every penny drawn from the rates two would go to officials. The medical profession is too apathetic to look after its own interests or it would use its influence to prevent the opening of school clinics or the municipalization of existing hospitals and dispensaries, and insist that children suffering from diseases which unfit them for mixing with others should be sent to their family doctors. Some may suppose that the organization of yet another public medical service would provide good salaries for those who entered it. But they should remember these clinics would introduce into each district a salaried man who would inevitably deprive all others in the

neighborhood of their ready money patients. The competition of out-patient departments has already been ruinous enough to private practitioners.

The question of removing the thyroid gland in certain cases was raised at the Dublin Academy *à propos* of a specimen shown by Mr. Gunn. On cutting into it large areas of calcification were seen to have replaced almost all the gland tissue. Two months had passed and so far no signs of myxedema had appeared. Microscopic sections looked like carcinoma. Sir Christopher Nixon thought it was not considered justifiable to remove the whole thyroid, as myxedema was considered certain to follow. Perhaps in this case there was an accessory thyroid. Professor Scott said one section seemed normal and another patch might be anything. Another speaker considered that section looked suspicious, but he would not like to definitely pronounce it malignant. In reply to these and other remarks, Mr. Gunn said he did not think myxedema was certain to follow; that the calcification was not true bone, and Professor White had seemed to agree that the tumor looked ugly, and certainly the patient was better without it.

An inquest twice adjourned has been held on account of five deaths on a steamer coming from Antwerp to Grimsby. On arriving in the harbor a message for medical aid was sent, and the Medical Officer of Health, Dr. Simpson, boarded the vessel and found that the five victims were Russian Jews (two men, two women, and a boy), who had been taken ill at 10 o'clock A.M. and were dead at noon. They had eaten food they had brought with them. Ptomain poisoning was suspected, but in view of possibilities the contents of the stomachs and remains of food were sent for bacteriological examination. Another steerage passenger paid the difference of fare and traveled in the saloon. The jury thought she might give some important evidence, and so the inquest is again adjourned, as it was thought she had sailed for America. The bacteriologist has not yet completed his investigtaions.

The death is reported of Surgeon-General G. H. Day, at the age of 85. He served through the Punjaub campaign of 1848-'49, taking part in several battles and receiving medal and clasp. Later he was engaged on the Northwestern frontier and the Umbeyler expedition, for which he was awarded another medal and clasp. He retired in 1879.

(From Our Regular Correspondent.)

NEW HOSPITALS FOR THE DISEASES OF WOMEN—THE NEW INSTITUTE OF HYGIENE—PELVIC SHADOWS—X-RAYS IN EXOPHTHALMIC GOITER—CUTANEOUS REACTION IN MEASLES—SCLEROSIS OF THE SKIN SIMULATING A MASK—RELIEF OF ANGINA PECTORIS—SEA BATHING FOR THE DISEASES OF WOMEN—FLOATING HOSPITALS.

VIENNA, November 28, 1908.

Two new hospitals for the diseases of women were opened in Vienna on October 21, in the presence of high officials and of eminent representatives of the medical profession in Austria and in foreign countries. Professor Schauta delivered an address on "The Construction, the Organization and the Purposes of the New Hospitals for Women," and acquainted his hearers with the magnificent plans of the buildings and with many important details of their arrangement. The new buildings contain rooms for the reception of pregnant patients and several rows of separate apartments for women ready for delivery; the internes and students are housed in the central building, while the nurses are accommodated in the western wing; a dispensary for obstetrical and gynecological cases is run in connection with the hospital, being housed in the main building; much space has been given to laboratories; lying-in patients have almost the whole western wing and some rooms of the central building at their disposal. The gynecological service has been given very good accommodations, and the needs of students are provided for by a large auditorium, wardrobes, a small lecture hall, a library, and a room for the records of the institution. A laboratory is provided for experimental pathology and an *x*-ray cabinet is also housed in one of the wings. In a few eloquent words Schauta honored the memory of Semmelweiss, whose monument, the work of Charlemon, he and Professor Chrobak had recently presented to the university. The closing words of the speech were addressed to the assembled students: "With the construction of this magnificent building an opportunity has been given to the students of medicine in Vienna to perfect themselves in one department of medical work. But with this opportunity a number of duties have been also imposed upon the student body, for it should not ever be said that the great expenses incurred in establishing the new institute have been made without bringing worthy results in teaching and in research. The State should feel sure that its pecuniary sacrifice is going to bring proper return for humanity, and the duty of the student will consist in helping to bring on such results by diligent and thorough work in the new institute." After Schauta's speech the guests of honor were conducted through the hospitals.

On October 23 the new Institute of Hygiene was opened with similar exercises. This institute is a model establishment both in the character of the buildings constructed to accommodate it and in the interior arrangements. The building is planned according to the most modern ideas and contains the Hygienic Institute, the Institute for General Experimental Pathology, the Serotherapeutic Department, and the Department for the Examination of Food Products. Professors Schattenfroh and Paltauf delivered the principal speeches at the exercises that attended the opening of this institute.

Speaking before the Medical Society, J. Robinsohn considered the so-called "pelvic spots" in sciatica and their interpretation as calculi of the bursæ. The name "pelvic spots" has been applied in röntgenology to some shadows first noted by Albers-Schönberg; these shadows are usually found in the neighborhood of the inferior spine of the ilium and of the horizontal ramus of the pubic bone; they are usually round or oval, and seem to be some sort of calcified material or concretions. Many interpretations of these shadows have been proposed, some claiming that they are phleboliths, others taking them for calcified lymph nodes, intramuscular concretions, and even exostoses, the pedicles of which were hidden. Robinsohn is of the opinion that the same unknown process which produces these pelvic shadows, which must certainly be looked upon as pathological appearances, may sooner or later affect for a time or permanently other organs in the neighborhood, among them the ureters and the sciatic nerve. The speaker demonstrated a patient—a young man of 28—who had been suffering from gonorrhea for eight years and from bilateral sciatica for three years. All methods of treatment tried heretofore proved quite useless. An *x*-ray examination showed typical shadows on both sides; in their round form and in their compactness they resembled perfectly the pelvic spots mentioned above. According to Robinsohn, the patient was suffering from sciatica because of a gonorrheal affection of the pelvic tissues.

Dr. Schwarz has tried the effects of *x*-rays in 40 cases of exophthalmic goiter. The principle of the treatment consisted in the property of the rays to diminish glandular activity. In exophthalmic goiter exposure to the rays is followed by diminution in the amount of secretion of the gland. Schwarz's results showed diminution of nervous symptoms in all cases and decrease in the rate of the heart in almost all; two-thirds of the patients stopped losing weight, one-half showed diminution of the exophthalmos and one-fifth showed decrease in the size of the thyroid gland. Especially interesting was the influence of this treatment upon the action of the heart; favorable effects were uniformly obtained, and, of course, greatly modified the prognosis of the disease. Still more important is the fact that the effects of treatment seem to last for a long time, because the diminution in the size of the gland continues even after the use of the rays has been stopped. The principal point of the technique of the treatment is to obtain as deep a penetration of the rays as possible. Exact dosage must be provided because the skin of patients with exophthalmic goiter is extremely sensitive to the effect of *x*-rays. The treatment should be continued for many months, as the good effects are often seen only after prolonged use of the rays.

Clemens v. Pirquet has studied the behavior of the skin toward tuberculin during the course of measles. The cutaneous test with tuberculin may be used not only for the diagnosis of tuberculous infection but also for the estimation of the changes in the reaction of the skin. Repeated tests of this sort usually show a gradual diminution of reaction in miliary tuberculosis and quite a typical temporary diminution in measles; the phenomenon was observed by v. Pirquet in one case of measles, but later Dr. Preisich of Budapest has

shown that it occurs generally in that disease. This diminution in the reaction is very regular in its occurrence and is so characteristic that it can be used for diagnostic purposes. Scarlet fever, German measles, diphtheria, typhoid fever and cerebral meningitis do not show any such phenomenon, but it is quite evident in vaccination; it may be supposed to occur in smallpox as well. The cause of the diminution of the reaction is to be sought in the absorption of the antibodies which are required to produce the response to the cutaneous application of tuberculin; this decrease in amount of antibodies during measles explains the frequency with which patients are affected with tuberculosis after having gone through an attack of measles.

At the last meeting of the Society of Internal Medicine Prof. H. Schlesinger presented a Russian clergyman who was treated in his wards. This patient suffered from some hardening of the skin, and because of this appeared as if he wore a mask, the yellowish discoloration of the skin adding to the deception. The greater part of the skin elsewhere in the body had likewise assumed a board-like hardness, and Schlesinger thought that the condition present was a general sclerodermia and pigmentation. The disease began during the last year in a somewhat sudden manner after the patient had carelessly exposed himself to the effects of great changes in temperature. One day he went about from house to house, not being dressed very warmly; he was treated to some hot drinks while in the houses of his parishioners and then went out into the intense cold air of winter. The very next day he felt some swelling in the neck, and this swelling very rapidly spread over the back. At the time of demonstration the hardened skin surrounded almost the whole trunk and affected also the neck, the face, the arms, the forearms, and the thighs. The face presented all the appearances of a mask; the eyelids were so affected by the hardening of the skin that the patient could not lift them from the eyes; the mouth could be opened, but very slightly. The patient complained bitterly about the feeling of tightness and oppression, which may perhaps have been caused by the difficulty he had in breathing; it is possible, too, that the circulation had been affected by the skin changes. The lesion upon the arms was favorably affected by regular massage and the internal administration of arsenic.

Dr. Max Herz of Vienna has tried an interesting method of preventing attacks of angina pectoris and of paroxysmal tachycardia. He had frequently observed that the complaints of patients with heart disease were often much lessened, especially in an acute attack, if they succeeded in relieving their stomach of accumulated gas by inviting eructations. In order to assist this act Dr. Herz has his patients take some water into their mouths, then lean as far back as possible and swallow the water. The bending backward stretches the esophagus while the close attention which the patient pays to the act of swallowing produces a sensation in the pharynx that results in expulsion of gas from the stomach. The eructation usually occurs during the time of swallowing or immediately after the fluid has reached the stomach, the gas escaping slowly on some occasions and on others very quickly with explosive violence, though in small amounts. In the latter case Herz has the patient repeat the maneuver. The amount of water swallowed should not be too large, because its only use is to allow the act of swallowing to take place and not to fill up the stomach with the fluid. The method must be learned by frequent practice during the intervals free from the attacks of heart trouble. Little by little the patient learns to expel larger and larger amounts of gas. Herz lays stress upon the necessity of explaining the nature of the method to the patient because such knowledge seems to help in the production of the results aimed at; the will of the patient may inhibit the act of eructation or further it. Herz had as good results with this method in paroxysmal tachycardia as in angina pectoris, for in both conditions an acute attack can be brought about by the accumulation of gas in the stomach.

The Association of Physicians has addressed the public, especially the women, in a little pamphlet and has impressed them with the importance of early recognition of the first signs of cancer, especially that involving the uterus; in another popular brochure it has called the attention of the public to the dangers of venereal disease; finally it called attention to the harmful effects of phosphorus upon the workingmen compelled to handle it and has asked the government to put an end to this danger by a radical prohibition of the use of phosphorus in some of the arts and not by any halfway measures which were proposed in some quarters.

Dr. Kurz of Abbazia spoke at a congress at that place on "The Action of Abbazia Sea Baths Upon the Diseases of Women." He came to the following conclusions: Observation of over four hundred cases of gynecological diseases warrants the statement that the bathing in Abbazia is of very great use in the treatment of such disease. If careful selection of cases is carried out the results of sea bathing in Abbazia are in no way worse than the results of treatment elsewhere, especially when compared to resorts with saline and thermal baths. Sea bathing should be looked upon as an independent system of treatment for disease, and not merely an after-treatment for convalescents. The climate of Abbazia makes it very suitable for a resort where sea bathing could be used as a therapeutic measure; such bathing could be enjoyed throughout the year, which is not possible in other resorts.

Dr. Diehm of Vienna stated his attitude on the question of floating sanatoria in the following words: The question of floating sanatoria has become a very important one at the present time. The need of ships equipped for this purpose is evident, and the call for them will increase in the near future, as their great value in therapy of disease will be more widely recognized. The desired construction and arrangements of such ships have already been well worked out, and the indications for sending patients for treatment in such hospitals have also received a great deal of attention recently. Such indications increase in number almost from week to week, as the benefits of the treatment become better understood. It is important that proper waters should be selected for the cruises of these hospitals, so that the patients might enjoy the effects of the sea air without interruption by bad weather. The Adriatic and the Mediterranean seas seem to be best adapted for such cruises; they offer all the climatic and weather conditions desired; the topographical relations of these waters, too, are best suited for the requirements of the inhabitants of Europe, which will probably furnish the greater number of passengers for the floating hospitals of the near future.

Progress of Medical Science.

Boston Medical and Surgical Journal, December 24, 1908.

Tuberculosis of the Larynx.—A. G. Getchell presents a general description of the subject. He says that a clear voice may persist even in the presence of marked infiltration. As to prognosis, he says that lesions of the cords or ventricular bands are more likely to get well than those of the arytenoids and epiglottis. Marked involvment of the arytenoids with grayish infiltration, with or without ulceration, he has never seen recover. Treatment is primarily one of the patient and secondarily of the larynx. Rest alone is often the best plan, and complete silence must be enjoined. Cough calls for rest, open air, soothing inhalations and suggestion. Intratrochial injections of guaiacol and menthol in olive oil are serviceable. Cleansing sprays should be used several times daily if the patients are strong enough. Iodoform is better for the ulcerations than is lactic acid, but if the lesions in the larynx are localized, the surrounding areas not actively inflamed, the lung lesion inactive, and constitutional symptoms not marked, curettage and lactic acid are indicated. For destroying areas of infiltration the best agent is the electro-cautery. For the hopeless cases the author advises cleansing and orthoform powder to relieve pain. When at the last more powerful sedatives are required, he uses the following powder: Paraformaldehyde and orthoform, āā 5i; compound zinc stearate, gr. xlviii; morphine and cocaine, āā gr. x.

Chronic Gout.—One case is reported by D. E. Keefe, who adds some general observations on the effects of uratic deposits on bone and cartilage, the effects of opening or puncturing tophaceous masses, causes of deposition of urates in joints and other tissues, and the effect of the gouty poison on the kidneys. Concerning the general effect of puncturing or opening the deposits, the author says that the procedure is analogous to laparotomy in tuberculous peritonitis in that we cannot positively tell whether it be the admission of air or the manipulations that furnish the required stimulus. But we do know that frequently immediate benefit ensues. In this case of gout the opening gave vent to the pent-up serum and the more liquid portion of the uratic deposit, while the admission of

air set up an oxidation process, thus causing liquefaction and discharge of the more solid portion. Be this as it may, a profuse discharge followed and the edema was lessened and improvement marked. The openings were dressed with simple water dressings, but carbonate of sodium or lithium dressings are preferable. There was a degree of arteriosclerosis present; the anterior tibial artery and many of the veins were nearly or quite occluded.

New York Medical Journal, December 26, 1908.

The Influence of Alcohol Upon the Public Health.—F. Peterson dwells upon the disastrous effects produced on the public health by the present alcoholic excesses, and estimates the economic loss caused thereby. He considers the current notion that alcohol is a food as disastrous, for it is a poisoned food. He notes that the present view is that alcohol is a depressant rather than a stimulant. It perverts digestion, depresses heart action, lessens the capacity for muscular work, diminishes the intellectual functions, brings about slow, far-reaching anatomical changes, such as fatty heart, kidney lesions, disease of the blood vessels, muscular and nerve tissue changes, and weakens the normal defenses of the body against infections, especially tuberculosis. Physicians should be missionaries for reform in the use of alcoholic drinks. The walls of French hospital wards are placarded with wise rules in this respect, and the author has placed on his own prescription blanks the following temperate statements: Alcohol is a poison. It is claimed by some that alcohol is a food. If so, it is a poisoned food. The daily regular use of alcohol, even in moderation, often leads to chronic alcoholism. One is poisoned less rapidly by the use of beer than by drinking wines, gin, whisky and brandy. Alcohol is one of the most common causes of insanity, epilepsy, paralysis, diseases of the liver and stomach, dropsy, and tuberculosis. A father or mother who drinks poisons the children born to him or her, so that many die in infancy, while others grow up as idiots and epileptics.

The Diagnosis of Acute Miliary Tuberculosis.—The paper of S. von Ruck closes with a bibliography of recent literature. The points he makes with reference to the differential diagnosis of this particular variety of tuberculous disease are the following: (1) The rapid emaciation which is a striking feature in almost every case, and which is out of all proportion to the degree of fever, the state of the digestive organs, and the amount of food taken. (2) The bronchiolitis of acute miliary tuberculosis of the lung is characteristic in that the catarrhal signs appear first in the smaller and then extend to the larger bronchi, instead of in the reverse order as in ordinary bronchitis. In further contrast to ordinary bronchiolitis the lower posterior portions of the lung in acute miliary tuberculosis are often less involved than the upper. (3) Cases in which typhoid fever is minutely simulated by acute miliary tuberculosis or in which the two diseases coexist are rare, and a careful study of the pulse, temperature, and respiration will usually lead to a correct distinction. (4) Serum reactions are reliable when present in well marked degree, but tuberculous patients may show a modified Widal reaction and the Arloing-Courmont reaction is not always present in tuberculosis. (5) The ophthalmic test as applied by Calmette and the cutaneous application of tuberculin according to the method of Pirquet, while not yet established as thoroughly reliable, are safe, and one or both should be employed in all doubtful cases, especially if the subcutaneous injection of tuberculin is contraindicated. (6) Bacteriological examinations of the blood, fæces, and secretions may be of great aid in doubtful cases. (7) The appearance of choroid tubercle or miliary tubercle of visible mucous membranes in the course of the disease removes all doubt.

Severe Ivy Poisoning.—R. F. Ward offers the following suggestions regarding treatment: The bowels are thoroughly cleaned out with calomel and a saline, and copious draughts of cool water are given to flush out the kidneys. This plan sometimes aborts an attack if it is put in operation immediately after the poisoning. If vesicles are already formed, loose gauze saturated with acetate of aluminum solution is applied. Ointments should be avoided until after weeping ceases. Then a ten per cent. ichthyol-vaseline may be used. For internal medicine the tincture of cypripedium (two to five drops) may be given every three hours until the subsidence of acute symptoms. It should then be continued thrice daily for two weeks. It aids the kidneys and stimulates healthful repair of the skin, and very markedly lessens the tendency to post inflammatory itching and burning. Under no circumstances are the surfaces rubbed or the vesicles evacuated. Slight rubbing during dressings may set up violent burning and intolerable itching, requiring a hypodermic injection of morphine. When sleep is disturbed because of peripheral irritation codeine sulphate, gr. ss. may be given at bedtime and repeated during the night if necessary. The diet should consist of milk and vichy or some other carbonated water, equal parts, alternated with simple, salt seasoned broths, and a few light vegetables. For two weeks after the local manifestations have disappeared the patient should be kept on a strictly vegetable diet. Experience has taught that meat given before this may cause a disagreeable return of cutaneous irritation, which often is most manifest when the air strikes the skin upon removing the clothing before retiring, and may not subside enough to permit a good night's sleep. Sequelæ are often wanting entirely, but occasionally eczema or furunculosis may supervene. It is therefore wise to give a hematonic consisting of some form of iron, arsenic, and strychnine, beginning as soon as the patient is up and around.

Journal of the American Medical Association, December 26, 1908.

Yellow Fever and the Mosquito.—J. H. White says that the only way to avoid errors of diagnosis between yellow fever and certain diseases that are likely to be confounded with it, and all the possible consequences of such confusion, is to extirpate all mosquitos, all stegomyiæ, all anopheles, and all culices. This seems easier than it is; it calls for an infinity of detail and almost superhuman perseverance and patience. He gives minute details of the measures necessary for the destruction of infection-bearing mosquitos of each of the types mentioned, the destruction of their breeding places, etc. This *Stegomyia* is a sort of human parasite, increasing with civilization, and the *Culex pungens* which carries dengue is the same to a lesser extent, the *Anopheles* are less domesticated and tend to decrease and disappear with cultivation of the soil and civilization. Each has its own habits, which are more or less known to us, and we must modify our measures accordingly. We are protected from yellow fever at present by a sea quarantine, but railway communication will soon be complete from Central America to the United States, and an efficient land quarantine is an impossibility. At the last analysis the only rational preventive of yellow fever is sanitation, not quarantine. What we must do is summed up by White as follows: "1. Destroy within our borders all disease-bearing mosquitos. 2. Follow the advice of Surgeon-General Wyman given in his letter to the Secretary of the Treasury, strongly urging that Havana and all other then existing danger points should be compelled to clean themselves. 3. Educate all young physicians as profoundly as we can in entomology and in tropical medicine, remembering that it is no small part of the duty of the physician to educate his people in sanitation. The blind may not lead the blind."

Mosquito Destruction in the Tropics.—J. A. Le Prince describes the conditions and methods of mosquito destruction in the Canal Zone. The malaria-bearing species of anopheles are all shade-loving, and, though they will bite at any time, there is no record of their biting in full sunlight. Whether in a shaded area they will bite malarial persons and remain there long enough to transmit it to other persons in the same place has not been settled, but seems possible. Some anopheles breed throughout the year on the Isthmus, and the larvæ have been taken in brackish water containing up to 90 per cent. of sea water. The difficulties of mosquito destruction in the tropics, as compared with more northern latitudes, are enumerated. They are: 1. The continuous propagation throughout the year. 2. This is especially a difficulty during the dry season, when the streams become stagnant and alive with the larvæ. 3. The rapid growth of algæ, etc., in the ditches, sheltering the larvæ and preventing their destruction by fish. 4. Owing to the great extent of drainage required on account of the heavy rainfall, it is impracticable to keep the waters free from such growth with the available labor. 5. The difficulty of finding all the breeding places in a climate where the rainfall is so great and the ground so saturated during a larger part of the year. 6. The necessity of keeping down the rapid growth of jungle which prevents evaporation and conceals breeding places of the mosquito. The methods used to destroy mosquitos are: Fumigation, used for dwellings, cars, etc.; crude petroleum,

which has not been very successful; larvacides; open ditches, which are useful if shallow and quick to dry up after a rain; blind drains, used before tile drains were introduced; filling in of depressions and low ground, and tile drainage, which has been found the most economical and permanent method of destroying anopheles in the tropics. Clearing away the tropical vegetation, which hides the breeding places and shelters the mosquitos, is an essential in all cases. With the use of all these methods, which are described in detail, the results have been exceedingly good. The malaria situation in 1907 was a vast improvement over that of 1906, and that of 1908 up to the date of his report is even better.

Slight Joint Traumas.—S. Lange calls attention to the clinical and medicolegal importance of slight, often apparently insignificant, injuries to joints. The histologic elements of the joints are of comparatively low organization and scant vascularity, hence degenerative and chronic inflammatory fibroid or calcareous changes are the more likely to occur. New bone or fibrous tissues thus started may act as an irritant and give rise to a progressive aggravation of the trouble. Thus what was at first a conservative effort of Nature becomes, in the synovial regions, an irritant, and each new conservative effort gives rise to more irritation. Too often this vicious circle accomplishes the ruin of the joint, especially in such joints as the knee, subject to rather violent motion and strain. These chronic joint changes are usually slow in developing; one to ten years may elapse between their inception and marked functional impairment. The causal trauma is thus often overlooked or forgotten. The *x*-ray is often the only means of ascertaining the actual conditions. The changes being progressive, the ultimate picture may not be unlike that of arthritis deformans, but this may be ruled out if the other joints of the body are found normal. Constitutional tendencies, however, may play an important part; in a patient with a distinct gouty or arthritic habit, the chances for chronic joint changes following trauma are much increased. The possibility of such changes following trauma must always be borne in mind and a guarded prognosis given in many cases, especially in persons over forty, and of a gouty or arteriosclerotic habit. The medicolegal importance of these facts is obvious, as they show how an injury received years before may be the real cause of serious disability, though it may not be easy to prove the direct causal connection in a given case. There is another type of joint trouble following slight trauma in which conditions are reversed. In this type the joint changes precede the injury, but the symptoms are latent until called into notice by the trauma. In arthritis deformans, for example, the symptoms may not appear till after some slight injury, though the joint changes may have existed for some time. When they are once lighted up by the trauma, they rarely disappear completely, but run the characteristic course with exacerbations and remissions. The possibility of an underlying arthritis should always be borne in mind when a traumatic joint inflammation fails to subside under the usual treatment. Lange reports a case of this kind in which accident insurance was claimed and allowed, as he believes justly. Although the chronic joint changes preceded the injury, it lighted up the symptoms, which then refused to subside. If the injury had not occurred, it is probable that the patient would have had the full use of the joint, perhaps for years. The good function of the corresponding uninjured joint, which showed the same changes to *x*-ray examination, was evidence of this possibility. The patient had, therefore, a just claim for damages or insurance, although the pre-existence of the chronic joint disease should have modified somewhat the amount of the claim.

Hemorrhage in the Newborn.—H. E. Tuley says that hemorrhage is an accident to which the newborn are liable; its etiology is obscure, but since fever is a prominent symptom in most cases, it is generally believed that it is due to septic infection. Newborn infants develop sepsis easily and there are many ways in which the offending organisms may attack them. Among other causative factors have been mentioned prematurity, atelectasis, cardiac abnormality, gastric or intestinal ulcer, thinness of the blood-vessels, congenital portal obstruction, hemophilia, and the changes taking place in the circulation incident to birth. The hemorrhage may occur in any organ and before or after birth. If after, it usually occurs within the first three days. If from the gastrointestinal tract alone, it is called malena; Tuley reports a case. Various methods of treatment have been recommended. The different hemostatics, the cold coil, etc. In the case reported subcutaneous injection of gelatin was followed by prompt recovery and two other cases are mentioned in which like results were obtained. Special caution is needed as to sterilization of the gelatin on account of the common contamination with the tetanus bacillus.

The Lancet, December 19, 1908.

Treatment in a Case of Arthritis Deformans.—F. Booth considers it as proven that in the case of the woman of twenty-nine years reported by him the disease resulted from autointoxication from poison generated in the large bowel, and to a less extent in the small. In his patient the administration of B-naphthol lessened the offensiveness of the stools. Irrigation of the colon checked the neuralgia and lessened the emaciation. For the irrigations two tablespoonfuls of epsom salts were dissolved in three quarts of hot water. The joints gradually became less swollen and tender, while the swelling and effusion slowly subsided. Subcutaneous injections of fibrolysis seemed to assist in bringing the joints back to a normal condition.

Streptococcal ("Septic") Throats.—J. O. Hollick, an English health officer, reports two epidemics, one in an asylum and the other in a boys' school. A third epidemic of scarlet fever is mentioned. In all three, the main organism present was a streptococcus, producing respectively tonsillitis, erysipelas, and scarlet fever. In the sore throat epidemic, the local features were angry red inflammation with creamy-white secretion, swollen and edematous uvula. No cryptic plugs on the tonsils, general febrile condition. The exudation rarely extended either in front of or behind the definite region of the femoral pillars, but much mucopurulent secretion was observed to come from the lymphoid follicles over the vault of the pharynx, and there seemed to be a general engorgement of the lymphoid tissue around the posterior nares. The foregoing condition lasted from two to four days, while the glandular swelling and tenderness in the triangles of the neck remained for some days or weeks after the throat closed up. Two of the cases developed erysipelas with marked septic symptoms. Antistreptococcus serum was given with relief to the constitutional symptoms, but the local conditions abated but little. There was in several of the cases a marked tendency to relapse if the patients were allowed up too soon. The author says that in such outbreaks thorough sterilization of all utensils employed about the patients should be insisted on.

The Mercurial Reaction as an Element in the Diagnosis of Syphilis.—F. Curioni has examined the urine in a series of cases of syphilitics and non-syphilitics respectively, all of whom were given mercury, and then noted the amount of the drug excreted by the two classes. His chemical technics are described in full. He came to the following conclusions: (1) The mercurial reaction in the urine of the healthy is much more evident than in the syphilitic, in which sometimes there is no reaction at all. This means that the elimination of Hg. in the urine of the syphilitic is always much slower than in the healthy. (2) The mercurial reaction is nil or nearly so in cases of syphilis recently contracted, especially when symptoms are apparent. The reaction is only slightly evident and never so well as in normal cases, in the syphilitics in whom two or three years have elapsed since the appearance of the ulcer. (3) Finally, in cases of long standing, say ten or twelve years, the mercurial reaction is as evident as in normal cases (positive reaction). These facts are explained on the following theory: In the first place, in the subject of syphilis, the mercury introduced perhaps unites itself in a special organic combination with the virus, for which, being a specific remedy, it must have a special affinity, and in this condition it does not pass, or passes only with difficulty, the renal filter, and at the same time does not have any offensive action on the organism. Thus in this fashion it would be easy to understand the old empiric advice to wait before commencing the general cure until the secondary symptoms have appeared and remain in view for some time. Some contend that the morbid evolution is milder and more regular if the general treatment is commenced rather later and not before the secondary symptoms. On the other hand, the rapid elimination in the pseudo-syphilitic is probably due to a vital tendency of the organism to expel whatever is noxious to it. For whatever concerns the intolerance to mercury observed in the pseudo-syphilitic, at least in the beginning of the

treatment, it lasts only until the specific antibodies of the mercurial antigen have not come to paralyze its poisonous action. The author believes that it is most probable that the antitoxic reaction which proceeds in the organism against these special poisons neutralizes their therapeutic action.

Treatment of Gout by Thyminic Acid.—Further observations on this topic are made by R. Fenner, who submits epitomized histories of six cases of acute and thirteen of subacute gout. He has had prepared a sterilized solution of the remedy equivalent to two grains of the powder for intramuscular injection, and experiments on animals showed that it was well born and harmless. It was then used on patients. Taking into account the chemical affinity of the acid, it is logical to assume that its local action would greatly lessen the deposition of the biurate of sodium in the joint or tissues. It is in the prevention of attacks of acute gout, in the obesity so often allied with the gouty state, in gouty eczema, asthma, glycosuria, and stomachic derangements that thyminic acid attains its maximum of usefulness. A small dose (4 grains) taken daily after meals for a prolonged period, say of three months, and then every alternate week, will in most cases entirely avert the onset of acute symptoms, and the author has a record of many patients who for the past three or four years have entirely escaped attacks that were formerly of constant occurrence. The remedy will not always break up an attack of acute gout, but it is useful in the later stages of an attack. The greatest benefit has also accrued to that very large class of cases where the apparent trouble is of gastric, hepatic, or intestinal origin. In obesity, which so often accompanies and is often the only symptom of the gouty state, the results are most gratifying. A gradual reduction of weight occurs without loss of strength. Nor need the patient be starved or nauseated by incongruous foods. In acute cases where we have to deal with an inflamed joint and accompanying pyrexia it is as well to combine the thyminic acid with colchicum or aspirin until the acute stage is passed. The days or weeks of intense depression, irritability, and want of energy so often observed are shortened by its continued administration and a recurrence of the attack averted.

British Medical Journal, December 19, 1908.

The Value of Turpentine in Gallstones.—A woman of 54 years came under the care of G. Wright, who found she had fever and suppurative inflammation of the gall-bladder. Cholecystotomy was performed, and the viscus, which was full of stones, was cleaned out. A large mass of impacted stones was found lying apparently in the ductus choledochus, but, on account of the adhesions round the gall-bladder, etc., the duct could not be properly exposed. A spoon was passed three inches or so through the cystic duct, but the stones could not be removed, and they were so hard that it was impossible to break up the mass or to make any impression upon it. The author suddenly recollected the well-known solvent action of turpentine on gallstones, and determined to try it. A piece of india rubber tubing was fixed on a small glass syringe and one drachm of turpentine injected through the cystic duct on to the surface of the impaction. In a few minutes he was able to break up the impaction, and in about ten minutes all the stones were removed from the duct. The patient made an uninterrupted recovery, the opening in the gall-bladder healing up in about six weeks. From his experience in this case it seems to me that the habitual use of turpentine in connection with cases of choledochotomy in which there is the slightest difficulty in removing the bile concretions might materially lessen the risks of the operation.

Retardation of the Pulse Wave in Aortic Regurgitation.—This phenomenon has been carefully investigated by Walter Broadbent, who notes that when simultaneous tracings of the carotid and the pulse were taken in cases in which the pulse delay was considerable, it was found that the interval between the carotid and the pulse was only slightly greater than the normal, so that the main delay evidently took place between the apex beat and the aorta. It occurred to him then that this delay might be due to the increased size of the heart, so he measured the distance from the apex to the aortic cartilage in subsequent cases; but he found there is no relationship between the size of the heart and the time of arrival of the pulse at the wrist, some of the largest hearts showing no delay. The systolic blood-pressure also seems to have nothing to do with the amount of delay. There is a rough correspondence between the extent of the aortic regurgitation and the amount of the delay, the greater the one the greater the other, and he thinks there may be found to be some relation to the compensation of the valvular lesion, there being increased pulse delay with failing compensation in some of these cases; of the seven cases with delay of one-third of a second he knows that three are already dead. The tracings taken from other than aortic cases show that increased pulse delay is not peculiar to aortic regurgitation. There was delay in two cases, showing signs of adherent pericardium. Both had an apex beat hardly moving on rolling the patient from one side to the other, diminished respiratory movement in the epigastrium. Tabulated statements of his detailed findings are included in his paper. Examination of the facts and figures given therein shows that there is frequently considerable increase of the interval between the apex beat and the pulse wave in some aortic regurgitation, while in slight rheumatic cases and in the majority of the atheromatous and syphilitic cases the interval is the normal one-fifth or less. In these latter cases there is usually not much regurgitation.

Occurrence of Heart-Block in Man and Its Causation.—T. Lewis presents a study of 27 cases of heart-block in man, compiled from the literature of the last few years. Post mortems were held in all, so that the condition of the bundle of His was definitely known. Many other cases have been reported during the period named, but the positive evidence which is recorded in the cases collated by the author has been to a greater or lesser degree lacking. Of the 27 cases, histological evidence was obtained in 17 to the effect that the bundle of His was damaged. We are not thus far able to determine an exact accord between the degree of the lesion and the amount of the heart block, but the clinical evidence clearly supports the following propositions: (1) No case of complete heart-block has been reported in which there was not grave reason to suspect complete functional discontinuity of the bundle, and (2) with a single exception no case of incomplete heart-block has been reported in which the bundle was demonstrated as completely destroyed at any single point in its course. The conclusion from these facts seems irresistible, but the author admits that in man alone such a proposition is barely demonstrated. Yet he regards accumulated evidence as carrying the proposition almost, if not quite, beyond the limits of hypothesis. The paper is extremely interesting.

Münchener medizinische Wochenschrift, December 15, 1908.

Induction of Labor.—Ilerff warmly defends the induction of premature labor in cases of narrow pelvis in preference to operative procedures at term. The mortality of hebosteotomy, for instance, is 4. 9 per cent. for mothers and 9.6 per cent. for the children. On the other hand, early induction of labor leads to less than one death in a hundred, so far as the mother is concerned, though the mortality of the babies is about twice that of hebosteotomy. The simplest and best method of inducing labor is the tearing of the membranes; the danger of infection is much less in this method than in any introduction of elastic bags, bougies, etc. The pains that follow the rupture of the bag of waters are usually very good and the necessity of further interference with the labor process is little more frequent than in normal labors.

Absence of Patellar Reflex in Functional Disease.—Hoesslin says that the knee jerks may be absent completely and permanently in cases of functional nervous disease. This absence may be due to congenital anomaly of the reflexes, which in some cases may have been caused by syphilis in the parents; it may appear after exhausting condition or disease, such as mania; very seldom the reflex is absent in cases of hysteria and neurasthenia. The mere absence of the patellar reflexes cannot, therefore, be interpreted as a sure sign of organic disease of the nervous system; the exceptions, however, are so few that such absence should immediately lead to a search for further symptoms of such disease.

Examination of the Blood for Parasites.—Stäubli offers a new method for this purpose. It consists in mixing a drop of blood with about ten to fifteen times the amount of 3 per cent. acetic acid and centrifuging the mixture. The usual mixing pipette used in counting white blood cells is well adapted for this technique. The sediment may be examined in a fresh state or after being dried and stained. So far, the experience with the search of the blood for trichinæ, for

malarial crescents, for spirochetes of syphilis, and other organisms has shown the great advantage of the method over the examination of a dried smear of the blood. The staining is done by any of the chromatin stains, such as Jenner or May-Grünwald, the only elements taking the stain being parasites and the nuclei of white cells, the red cells having been completely dissolved by the acetic acid.

Deutsche medizinische Wochenschrift, December 3, 1908.

Treatment of Inoperable Carcinoma of the Uterus.—Freund says that even in cases of carcinoma of the uterus which cannot be removed radically surgical treatment remains the only one that gives some relief from symptoms and temporarily at least alleviates the sufferings of the patient. The loss of blood, the fetid discharge, the absorption of toxic material from the broken down cancer may all be put a stop to by a proper operation in the late stages when cure is impossible; it is also possible to prevent the rapid progress of the malignant process for months and even for over a year, as Freund's experience proves. The improvement is probably due to the removal of the peritoneal ascites, to the freeing of important organs from mechanical and chemical injuries caused by the growth, and especially to the great capacity of the healthy tissues to oppose the progress of the disease by encapsulating and limiting them for a time at least. One of his cases showed at the operation that the bladder wall was attacked by the growth, yet the viscus remained without perforation for two years after the operation. The important thing to remember is that cancer of the uterus may be very fast-growing in one case and very slow in another; operation may therefore relieve the latter case very much and for a considerable period of time. Operation by the abdominal route, with the removal of as much diseased tissue as is possible, is therefore indicated even in very advanced cases of uterine cancer.

Filariasis.—Zur Verth says that the *Filaria sanguinis hominis* is the larva of a much larger worm than usually lives in connective tissue and is only seldom found in the larger lymph or blood-vessels. The larva is much smaller than the adult worm and lives in the lymph or the blood. There are several species of this worm, among them the *Filaria loa*, with its larva, the *Filaria diurna*, that circulates in the blood in daytime. His case of *Filaria loa* was in a workingman who became infected in Africa. The symptoms consisted of initial fever and chills; several months later swellings began to appear in various parts of the body, the swellings not being permanent, but apparently wandering from place to place. Various subjective phenomena, such as pruritus and paresthesiæ, were associated with the swellings. On one occasion the patient caught sight of the adult worm appearing through the thin skin over a swelling. The blood showed the presence of the larvæ on one occasion only, though numerous searches were made; an eosinophilia of from 40 to 50 per cent was constantly present. The treatment should consist in the removal of the worm if possible. The patient should be instructed quickly to paint a ring of collodion about the worm if it appears under the skin and immediately call in a physician to remove the worm; possibly the use of a suction cup may be enough to keep the worm from escaping. *Filaria Bancrofti* with its larva *Filaria nocturana* leads to a different symptom-complex, the most striking feature of which is the development of elephantiasis. The case of zur Verth was observed in a woman who went to Africa as a school teacher, who suffered from several attacks of fever and finally developed elephantiasis of the ankle region. Her blood, too, showed a constant kosinophilia of 50 per cent. The third form of filariasis is due to *Filaria perstans*, the larvæ of which may be found in the blood both at daytime and in the night.

Proteid Metabolism in Obesity Cures.—Richter says that the important part of all obesity cures is to effect a loss of weight at the expense of the fat of the body while sparing tissue proteid. Loss of proteid beyond the amount introduced in the food is of serious moment, if constantly present during the cure. Such loss occurs in several systems of treatment recently proposed, as, for example, in the exclusive milk diet. He has performed complete metabolism experiments on several persons undergoing treatment for obesity according to the so-called "potato cure," the diet consisting of a cup of coffee, a roll, and forty grams of ham at eight o'clock, of one egg at ten, of six plums at twelve, of a plate of soup and 200 grams of potatoes, 100 grams of lean meat, of green salad, etc., at two, of a cup of coffee at four, of some fruit at six, and of another 200 grams of potatoes with some cold meat and cheese at eight o'clock in the evening. In all cases the nitrogen metabolism was either at equilibrium or showed a positive balance, while the weight showed gradual and steady diminution. As the protection of the muscle and organ proteid is of paramount importance, obesity treatment on the style of that sketched above may be safely used, even though the value of the diet in calories is only about one-half of that present in the amount of food usually taken.

French and Italian Journals.

Tuberculous Rheumatism and Inflammatory Tuberculosis.—Antonin Poncet claims to have discovered a form of tuberculosis that is similar to other infectious diseases, in giving the symptoms of articular rheumatism without the production of tuberculous deposits in connection with the joints. This is caused by the tuberculous toxin circulating in the blood and attacking serous membranes. It may attack the articulations, serous linings of cavities, etc. It simulates every manifestation of ordinary rheumatism, acute and chronic, and attacks the heart, skin, kidneys, meninges, nervous system, etc. It is of frequent occurrence, tuberculosis being so frequent. Inflammatory tuberculosis also exists, tuberculosis of the joints without tuberculous deposits. There are in these articulations neither alterations, nor exudate showing any tuberculous new formations. These lesions are exclusively inflammatory. The process affects the joints, serous cavities, and all the body structures. It causes passing and chronic inflammations and cirrhoses. It is an infectious and contagious process, caused by the bacillus of Koch. These conditions arise from the presence of attenuated nonvirulent tubercle bacilli. There are three forms of tuberculosis: Specific tuberculosis with tubercles; inflammatory tuberculosis with a mild reaction, as in intoxications, and tuberculous septicemia without appreciable lesions resulting.—*Gazette des Hôpitaux*, October 6, 1908.

Obstetric Operations in Dystocia from Deformities of the Pelvis.—Pinard gives the result of eighteen years' experience at the Baudeloque, during which period 46,249 cases have been delivered, with 141 symphyseotomies and 30 conservative cesarean sections. He believes that symphyseotomy is appropriate when dilatation is complete, in a healthy mother who is a primipara. No force should be applied in delivery of a deformed woman for fear of injury of the soft parts. In general, pregnancy should never be interrupted in deformed pelvis, when the child is alive; forceps or version should never be used in such cases; the cesarean section should be done or symphyseotomy. The Porro operation is appropriate only when infection has taken place or when osteomalacia is the cause of deformity. The indications for the conservative cesarean section are extreme deformity of the pelvis, or less marked deformity when labor has been very long and there is reason to believe that the life of mother or child has been endangered. No intervention should take place until labor has begun. In the last four months the author has done twelve conservative cesarean sections; all the mothers are alive and well and all but one of the children except one syphilitic child.—*Le Bulletin Médical*, November 18, 1908.

Hematological Formula and Significance of Leucopenia in Basedow's Disease.—Nicola di Giovine describes his examinations of the blood reactions in four cases of Basedow's disease, in which the diagnosis admitted of no mistake. He gives the histories of these four women in detail. He ends with his conclusions as a result of the examinations. There are constant blood alterations in those sufferings from Basedow's disease, especially morphological ones, which are most important. They are lessening of hemoglobin, diminished globular value of hemoglobin, alteration of the numerical relations between the red and white blood corpuscles, the white being notably diminished in number, diminished leucocytes, especially polynuclear neutrophiles, and in less degree of eosinophiles. This alteration of the blood is in relation with the alterations of the thyroid, being absent when the thyroid is not enlarged. The principal alteration, the leucopenia, is in relation with a diminished leucopoietic action of the bone marrow, probably produced by an inhibiting action of special retrogressive products of metabolism, which are not neutralized by the thyroid. Such hematological alteration is not serious nor permanent. It constitutes a valuable aid in diagnosis of this disease.—*Giornale Internazionale delle Scienze Mediche*, November 15, 1908.

Book Reviews.

THE BONE MARROW. A Cytological Study, Forming an Introduction to the Normal and Pathological Histology of the Tissue, More Especially with Regard to Blood Formation, Blood Destruction, Etc. Together with a Short Account of the Reactions and Degenerations of the Tissue in Disease. By W. E. CARNEGIE DICKSON, M.D., B.Sc. Edin., F.R.C.P. Edin. Lecturer on Pathological Bacteriology and Senior Assistant to the Professor of Pathology in the University of Edinburgh; Assistant Pathologist to the Edinburgh Royal Infirmary. With Colored Plates and Microscopical Photographs by RICHARD MUIR. London: Longmans, Green & Co., 1908.

THERE is no doubt that the bone marrow has been much neglected in the recent development of medical science when the study of the blood received so much attention. Yet these two tissues are so intimately dependent upon each other that ignorance of the conditions met with in one of them necessarily carries with it ignorance of many important facts in the structure of the other and the changes it undergoes in the normal life of the organism and in disease. Our hematological atlases and treatises leave little to be desired, yet Dr. Dickson's work is the only really important monograph on the subject of bone marrow. The difficulty of handling the material for a satisfactory study is one reason for this condition of affairs, the other being the few possibilities we have of studying the reactions of this tissue in the living person. The text of Dr. Dickson's volume consists of several chapters on the anatomy and histology of bone marrow, the reactions of this tissue in disease being especially considered. Then the cytology of the marrow receives attention, the morphology, and the sources of the various cells being treated at length. These chapters, beyond the interest they possess *per se*, throw a great deal of light upon the changes met with in the blood and broaden very much the conception of blood diseases as a class. The text is followed by a series of splendid plates giving a vivid picture of the phenomena that take place in this tissue which is so rarely considered in the usual discussions of the reactions of the organism to the abnormal conditions of disease. Among the most beautiful of the plates one shows serial sections of a giant cell, another gives the varieties of white cells met with in the marrow, and a third pictures cells modified by various injuries. Microphotographs illustrate the general appearance of bone marrow and photographs of cross-sections of the long bones give the gross pictures of this tissue in health and in disease. We cannot cite further examples among the plates and must simply express our admiration for the work of the author in preparing such valuable material and of the artist, Mr. Richard Muir, in picturing it by means of photographs and colored drawings. The monograph ought to occupy an honored place in the library of every physician who is interested in the modern study of the blood or simply appreciates the significance of the wonderfully varied cellular elements that compose the tissues of the body

GENERAL PATHOLOGY. By Dr. ERNST ZIEGLER, Professor of Pathological Anatomy and of General Pathology in the University of Freiburg in Breisgau. Translated from the Eleventh German Edition (Gustav Fischer, Jena, 1905). Edited and brought up to date by ALDRED SCOTT WARTHIN, Ph.D., M.D., Professor of Pathology and Director of the Pathological Laboratory in the University of Michigan, Ann Arbor, Mich. With 604 Illustrations in Black and Colors. New York: William Wood & Company, 1908.

LITTLE need be said about this volume because Ziegler's text-book has been for twenty-five years the most popular treatise on pathology among students and physicians of Europe and America. The eleventh edition is the last to be issued under the personal supervision of the author, who died in his fifty-seventh year, a few months after the book appeared. Dr. Warthin's translation, therefore, places the book before the English-speaking readers as the last word of a famous teacher, who devoted his life to perfecting this treatise by constant improvements in material and illustrations; although his pathological investigations led him into many scientific controversies, he possessed the highly judicious faculty which enabled him to keep his treatise always free from subjectivity and one-sidedness. Among the new matter of this edition we find noted researches on spirochetes and on the parasites of malaria; the relation of trypanosomata to disease; the new lore in regard to agglutinins, precipitins, cytolysins, and hemolysins; the more important researches in the histogenesis of tumors; recent developments in the interpretation of the phenomena of inflammation, etc., etc. Many sections of the original text have been completely recast to bring them in harmony with the latest developments in the science of pathology; Dr. Warthin has added such new facts as have been brought out since the issue of the German edition three years ago. The classified bibliography has likewise been brought up to date, American investigation having received due share of attention; this feature of the book forms a most valuable means of reference to the important pathological literature of the last quarter of a century. In short, this edition upholds the reputation of the work as the model text-book on the subject of pathology; its use as a class book will go far toward proper instruction of the medical student in the important subject it considers.

SUBCUTANEOUS HYDROCARBON PROTHESES. By F. STRAUSS KOLLE, M.D. New York: The Grafton Press, 1908.

THE author of this little volume has done a creditable piece of work in describing within small compass the details of various cosmetic operations about the face, neck, and shoulders. In spite of the scant esteem in which this branch of surgery is held, there is a real need for prothesis in certain unfortunate individuals whose personal appearance prevents them from earning a livelihood commensurate with their mental abilities. Dr. Kolle has searched the literature of his subject thoroughly, and the 120 references he furnishes are by no means the least valuable part of this work. There are chapters on methods, untoward results, instruments used, preparation of site of operation, indications for operation, and a classification of the various deformities to which prothesis is applicable.

DISEASES OF THE SKIN AND THE ERUPTIVE FEVERS. By JAY FRANK SCHAMBERG, A.B., M.D., Professor of Dermatology and Infectious Eruptive Diseases in the Philadelphia Polyclinic and College for Graduates in Medicine; Diagnostician to the Bureau of Health and Consulting Physician to the Municipal Hospital of Philadelphia; Fellow of the College of Physicians of Philadelphia; Member of the American Dermatological Association. Fully Illustrated. Philadelphia and London: W. B. Saunders Company, 1908.

THE scope of this book is somewhat broader than that of the usual dermatological treatises, for it considers all morbid processes that are characterized by cutaneous manifestations. The greater part of the volume is devoted, of course, to the diseases of the skin proper; these are considered under the headings of anemias, hyperemias, inflammations, hemorrhages, hypertrophies, atrophies, new growths, and neuroses. Most attention is paid to the symptoms and treatment, pathology being briefly stated. The lesions are illustrated by photographs, most of which are very good; a few, however, give no idea whatever of the natural appearances, because of the lack of colors. The exanthemata are then treated at length so far as the skin manifestations are concerned; differential diagnosis is fully considered. The final pages of the book are devoted to acute infectious diseases, such as typhoid, meningitis, etc., that are often accompanied by skin eruptions. A special chapter treats of actinotherapy and radiotherapy in dermatology. The book is a clear and concise account of the subject of dermatology and is especially adapted for use as a text-book.

L'ALIMENTATION À BON MARCHÉ par JEAN LAHOR et le Dr. LUCIEN-GRAUX. Paris: Felix Alcan, 1908

THIS volume concerns itself chiefly with the economic problem of cheap food. The authors believe along with nearly everyone else that we all eat too much meat. A list of eatables is furnished in an appendix stating how to nourish three persons during the winter season on soup, jelly, dry biscuit, onions, and the like.

LES TUMEURS DU SEIN. Par V. CORNIL, Professeur à la Faculté de Médecine de Paris; Membre de l'Academie de Médecine, Médecin de L'Hotel Dieu. Avec 160 figures dans le texte. Paris: Félix Alcan, 1908.

THE frequency of breast tumors and the difficulty of diagnosing some of them and especially of differentiating malignant growths from benign ones has led Professor Cornil to issue this volume devoted to the subject. He has collected representative neoplasms from his vast material and has given histological description of the findings and an illustration of the microscopical picture of them. Tumors of the mammary glands of animals are also represented by several specimens, so that the student of comparative pathology finds valuable material in this book. The monograph is a very welcome addition to the pathological literature of the day.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held December 4, 1908.

DR. CHARLES H. PECK IN THE CHAIR.

Intrascapulo-Thoracic Amputation for Sarcoma.—Dr. ASPINWALL JUDD presented a young woman, age twenty-six, who was operated upon twice for a tumor pronounced sarcoma. In September, 1907, she entered Dr. Judd's service at the Post-Graduate Hospital. Examination disclosed a mass incorporated in the outer shaft of the humerus, having all the characteristics of sarcoma. This mass was spindle-shaped, and increased the bulk of the bone about threefold. A second mass occupying the axilla and seemingly attached to the external border of the scapula and its glenoid projection was made out, about four by two inches in size. An atypical intrascapulo-thoracic amputation was accomplished, the axillary vessels being tied at their beginning, the plexus of nerves cut five minutes after blocking with a two per cent. solution of cocaine. The external border of the scapula, together with its anterior and posterior muscles, and the neck of the scapula were found involved. These muscles were cut away between two and three inches from the site of the growth and the scapula sawn through. The outer half of the clavicle was also removed. The recovery of the patient was uneventful. Within six weeks after the operation a small, very tender mass about the size of a bean was felt, occupying about the site of the cut plexus. This had not increased in size, and he was under the impression that it was a neuroma. The patient had gained nearly thirty pounds in weight, and remained in perfect health up to the present time. This case was one of a series of three resections of the shoulder girdle done by him during 1907. In the other two cases he found it more convenient to make an incision and tie the subclavian vessels and certain branches of the thyroid axis before proceeding with the operation. In all three cases the operation was practically bloodless. In the first case, that of a malignant enchondroma weighing twenty-seven pounds, the patient progressed very satisfactorily for four days and then suddenly died of embolism. The third case from last reports was quite as well as the one shown. In none of these cases was there any shock. This he attributes to the blocking of the nerves with cocaine. If care were taken to tie the axillary or subclavian vessels and such branches of the thyroid axis as supplied the affected part, the operation was practically a bloodless one, was not at all difficult of performance, and the results attained were comparatively satisfactory. The percentage of mortality was low for so grave an operation, according to latest statistics, including all cases about eleven per cent. The danger of recurrence in delayed cases was very considerable, about sixty per cent. dying of metastases within five years.

Resection of the Stomach for Carcinoma.—Dr. JUDD presented a woman, thirty-two years of age. This was one of a series of six cases operated upon by him for cancer of the stomach in September of this year. The physical examination before operation disclosed no tumor until after inflation of that organ with air, when a mass, freely movable, could readily be made out at the site of the pylorus. The patient was in fair condition, though anemic, and entered the hospital on account of gastric hemorrhage. After an initial incision along the left border of the rectus muscle, the stomach and duodenum, both unusually freely movable, were brought out, and an examination showed a carcinomatous mass occupying the pylorus and about one-quarter of the lesser curvature of the stomach. A Hartman-Mikulicz excision, as done by the Mayos, was then performed, escape of stomach and duodenal contents being prevented by means of properly protected Kocher clamps. The glands along the lesser curvature near the pylorus were found involved and resected, and a gland lying immediately behind the duodenum, also involved, was enucleated. As the duodenum was so freely movable, he attempted to join the open end of the duodenum to a portion of the open end of the stomach by means of the early Billroth method. No leakage occurred. The wound healed by first intention. The patient made an uneventful recovery, gained twelve pounds in weight, at the present time had ninety per cent. hemoglobin, and appeared in perfect health. Owing to the early stage and comparatively non-malignant character of the growth, adenocarcinoma, and the fact that he was enabled to enucleate all of the apparently affected glands, this seemed a rather favorable case. The joining of the cut ends of the stomach and duodenum was contraindicated in most cases, owing to the danger of leakage, as, unless the duodenum was very freely movable, the tension upon the stitches was apt to prove disastrous. This occurred in the second case of this series and death resulted.

Resection of the Colon for Tuberculosis Primary in the Appendix.—Dr. JUDD presented a young woman of twenty-six, who was referred to him with the diagnosis of recurrent appendicitis. Pulse and temperature were only slightly elevated. The attack was the fourth in three years and had lasted for twenty-four hours. The diagnosis seemed clear enough. A modified Kammerer incision disclosed the appendix almost completely replaced by tubercular material. The ascending and most of the transverse colon were also degenerated and studded with tubercles, and the mesenteric glands were found involved in the process. The Kammerer incision was extended upward for a distance of three inches, and after isolating, Kocher clamps were applied to the ileum and transverse colon about three inches from the splenic flexure. The cut was then resected in the usual manner, and the ileum united by lateral anastomosis to the stump of the transverse colon after loosening its mesenteric attachment. No difficulty whatsoever was found in bringing the ends of the intestine together. In fact, in all the cases that he had had or seen this had proved no obstacle to the accomplishment of a satisfactory anastomosis. The patient had an uneventful convalescence, had gained forty pounds in weight, and was the picture of health. This was one of five cases of primary tuberculosis of the appendix operated upon by him during 1907-8. In the second and third the tubercular process was confined almost entirely to the appendix. In the fourth the caput coli was also involved. In the fifth and last case the patient was referred to him for secondary operation for fecal fistula following operation for appendicitis five months previously. The fistula was so large that the patient was rapidly starving to death, weighing one hundred and seven pounds when referred to him. On operation, much the same condition was found as in the case reported, and the operation performed was a similar one. Primary union and rapid convalescence occurred, but unfortunately the patient had died within the last month from tubercular pneumonia following an attack of influenza.

Double Amputation of the Breast for Carcinoma.—Dr. JUDD presented a young woman, twenty-nine years of age, who was operated upon by him five weeks ago. Her physical examination before operation showed a mass, irregular in outline, about 3 x 1½ inches in diameter, typically carcinomatous, occupying the upper and outer quadrant of the left breast. The axillary glands were palpable and apparently slightly involved in the malignant process. The right breast was apparently somewhat larger than normal, but taken by itself would not have excited suspicion; the glands in the right axilla were aglutinated, considerably enlarged, and, in view of the findings in the left breast, extremely suspicious. The left breast and axillary contents were removed, the Myers-Halsted operation being per-

formed. An incision was then made in the right axilla, and a frozen section, examined by Dr. Henry Brooks, was returned with the report of undoubted carcinoma. The right breast and axillary contents were then removed in the same manner as the left, in this case it being necessary to remove the infraclavicular glands, as they were also involved. Primary union resulted. The patient left the hospital at the end of ten days. The interesting point in this case was the double involvement, together with the absence of apparent primary lesion in the right breast. Subsequent examination of the right breast showed a very small beginning carcinoma.

Formation of New Tibia Following Complete Loss of the Diaphysis from Osteomyelitis.—Dr. Joseph B. Bissell presented a boy, whose weight was ten pounds and three ounces, of healthy parentage. Last July, while at the seashore, a small abscess developed over the mental prominence to the right of the middle line. This was opened and it healed rapidly. Following this the baby developed an acute attack of colitis, which subsided in about seventy-two hours. Immediately following this intestinal infection, a point of inflammation appeared at the junction of the upper and middle fourth of the tibia anteriorly. This grew rapidly worse and developed into an abscess which was open and discharged pus. A new point of infection developed over the lower portion of the tibia at its crest; within forty-eight hours another point of infection appeared low down in the calf muscle. As the cavity of the upper abscess seemed to be very deep, a drain was pushed through near the lower part of the popliteal space. In a few days these lower abscesses were opened and a drain connecting them was inserted. The upper and lower part of the tibial infection were then connected and drainage was carried through these openings. During the following two weeks of treatment an abscess developed over the left sternoclavicular junction. Later two small abscesses developed in the periosteum of the skull posteriorly. These were opened, drained, and healing took place without incident. In the meantime, the sinuses of the tibia were treated by free drainage, constant irrigation, and Bier's cups. On August 19, on removing some pieces of dead bone from the upper sinus, he discovered that the main portion of the bone seemed to be gently rotating in the forceps. All of the tibia from the epiphysis above to the epiphysis below, *i.e.* the entire shaft of the bone, came away without any difficulty. Daily irrigations were continued until, by September 25, the openings closed. In order to prevent fracture of the fibula, which did not seem to be infected, and to prevent deformity of the leg, a plaster of Paris splint was applied. The present solidity of the bone could be shown by contrasting the bones of the leg with the fingers, as shown in the *x*-ray plate. The baby now weighed fourteen pounds. Dr. Bissel said he presented this case because of its rarity, the early age of the subject, and the extensive involvement of the disease. There was a complete and rapid recovery. Reduplication of bone from the periosteum and the epiphysial centers was not rare theoretically; practically, however, they met with few cases showing such marked results. The extensive metastases which took place added to the difficulty, and made the case still more unique and worth more than a passing notice.

Primary Carcinoma of the Liver.—Dr. Frank C. Yeomans presented this case. The patient was a woman, thirty-seven years old, a housewife by occupation. The family history was good. Five years ago she had a double salpingitis and local peritonitis, accompanied by a severe gastritis. She made a good recovery under local treatment. Prior to the time she had peritonitis, she suffered from occasional bilious attacks, but subsequent to that they became frequent, occurring two or three times a week. These attacks consisted of nausea, vomiting of food and bile, headache, and general prostration. These attacks persisted intermittently for one year; then she noticed some gaseous distension of the abdomen, and had pain in the right hypochondrium. The pressure of her clothing was distressing and often excited vomiting. During 1905 and 1906 she had frequent "sinking" spells when reclining. There were no chills, rarely did she have any fever, and jaundice was never present. The distension increased slowly and she became progressively weakened. The physical examination on September 15, 1906, showed a marked prominence in the right hypochondrium. On palpation a firm, oval tumor was felt extending from the right costal margin downward an inch below the navel and slightly beyond the midline, and moving with respiration. On percussion flatness was present over the entire area occupied by the tumor. A tentative diagnosis of tumor of the kidney or liver was made. Operation was performed on September 17, 1906. Upon opening the abdomen it was evident that the tumor was in the right lobe of the liver. The fundus of the gall-bladder felt normal, but the size of the tumor precluded palpation of the bile ducts. The surface of the tumor was markedly congested and was traversed by a network of large veins. When the tumor was incised, about twelve ounces of bloody, odorless fluid escaped. Many trabeculæ were broken down with the hand, and great quantities of soft, degenerated tissue were removed from the walls of the cavity, which was about the size of a grape-fruit. Rubber drainage tubes were inserted and the cavity loosely packed with gauze. The time of operation was forty minutes. The discharge from the wound was very large in amount, dark and offensive, containing much detritus; it soon assumed the offensive odor characteristic of cancer. After the tenth day the discharge slackened quite abruptly, and the patient was removed to her home on the eighteenth day. The sinus closed four weeks later. Since the operation, now over two years ago, the patient had enjoyed excellent health. Primary carcinoma of the liver was a rare affection; according to Eggels, it occurred once in two thousand fatal ailments coming to autopsy.

A Reversed Form of Madelung's Deformity of the Wrist.—Dr. DeWitt Stetten presented this patient. She was twelve years of age, and had never had rickets or sustained serious injury. About ten months before her mother had observed that there was a deformity of the left wrist, which gradually progressed, and about five months afterward a similar condition developed on the right side, but in a lesser degree. The case showed all the features which at present were more or less generally recognized as being characteristic of a Madelung deformity, with the following exceptions: (1) There was present an apparent posterior dislocation of the wrist. (2) The lower surface of the radius was turned backward instead of forward. (3) An anterior dislocation of the lower end of the ulna existed instead of a posterior one. (4) There was an increase in extension and a limitation of flexion instead of the reverse, as in the regular cases. The lateral bowing of the radius and deviation of the articular surface toward the ulna with the typical arrangement of the carpal bones and the limitation in abduction with increased adduction were present, as in the usual cases. But one other case of this backward form of a Madelung deformity had been recorded in literature. This was described by Kirmisson in 1902, and was almost an exact duplicate of the case presented. Dr. Stetten said that he had made a careful study of literature and had collected the reports of sixty-three cases of Madelung's disease, of which sixty-two were of the forward variety, and from the mass of contradictory evidence on this subject he had unravelled the following conclusions: 1. The so-called Madelung's deformity of the wrist was due to a bowing of the radius, usually of the shaft proper, occasionally of the epiphysis, and sometimes of both. This produced a deviation of the articular sur-

face and an apparent subluxation of the wrist. The deformity was usually bilateral. It bore a striking analogy to the genu valgum and genu varum of adolescence. 2. Heredity, the female sex, and youth (about eleven years) were predisposing factors, and the exciting cause was an irregular ossification of the distal extremity of the diaphysis, or of the proximal portion of the epiphysis, or both. Rickets, trauma, or inflammatory conditions seemed to be in no causative relation to the disease. 3. There were two distinct types, a forward or common one, and a backward or rare one, in both of which, however, there was generally an exaggeration of the normal curvature of the radius toward the ulna. A correspondingly increased inclination of the joint surface toward the ulna resulted with adduction of the hand and an angulation of the first row of carpal bones. 4. The disease was one of the growth period, developing spontaneously, with pain, and progressing gradually (two or three years), with limitation of motion against, and increase of motion in, the direction of the deformity. Numerous conditions simulated the lesion, but the history and the *x*-ray would establish the diagnosis. 5. The prognosis was good and treatment consisted in osteotomy of the radius after the disease had run its course and the symptoms or deformity justified surgical intervention. Linear osteotomy should be performed in mild, and cuneiform in severe cases. 6. Dr. Stetten said that he could suggest the terms forward and backward idiopathic progressive curvature of the radius for the condition, or the orthopedic names of carpus varus or carpus valgus.

Foreign Body Cyst of the Palm.—Dr. EUGENE H. POOL presented a man, forty-two years old. Twenty-five years ago, while attempting to remove a cartridge that was embedded in the chamber of a gun, he hammered it; this caused an explosion and resulted in a small, punctured wound. A two-inch incision was made, and the surgeon looked for a foreign body, but none was found. Later a small movable body, about the size of a bean, was noted in the palm, and this increased in size. The only functional impairment caused by this was that, as the patient stated, "his hand gave out." Fluctuation could be obtained over the swelling. A cyst was diagnosed. Under general anesthesia the cyst was removed, and in the center of this cyst was a piece of the brass shell of the cartridge. It was impossible to state definitely whether or not this was an implantation cyst.

Carcinoma of the Tonsil.—Dr. ALBERT A. BERG presented this case. The patient was a Hungarian, who gave a history, showing that during the past year he had had trouble with his throat, and during the last few months he had developed a large tumor mass and swellings in the neck, with characteristic radiating pains and difficulty in swallowing. There was not much difficulty in breathing. An examination revealed a large mass of adherent glands in the submaxillary and occipital triangles. Examination by mouth showed a large fixed tumor which corresponded to the right tonsil. This was found to be an ulcerating carcinoma. After temporarily ligating the common carotid artery on the right side, an incision was made which extended upward to the angle of the mouth, the jaw was sawn through in an oblique direction, the mucous membrane of the mouth was divided, and the tonsil and surrounding tissues excised. There was practically no bleeding. An uninterrupted convalescence took place. There was at present a small fistula resulting from a piece of necrosed bone.

Horseshoe Kidney.—Dr. BERG presented a patient who gave the following history: He was supposed to have had tuberculosis of the kidney and had been under medical treatment for some time, but without improvement. The cystoscopic examination was not successful. One year ago he became very much emaciated. There was a continuous desire to pass urine. The urine was purulent and contained some blood, pus cells and a few hyaline cylinders. The bladder was so contracted that it held but one ounce of urine. He catheterized what he supposed was the right kidney, and later he exposed what he believed to be the right kidney. He found a perinephritis and a horseshoe kidney. It was impossible in this case to determine the relations of the ureters; in fact, he could not tell whether there was one or whether there were two ureters. The kidneys were studded with tubercles. There were no other evidences of tuberculosis. The capsule of the kidney was split, and, after three weeks, the patient was sent home in the country. Two urinary fistulæ appeared, which remained open eleven months. The patient showed good results from simply a climatic treatment. Prior to this experience Dr. Berg said he was inclined to operate in cases of horseshoe kidneys; but in view of his experience with this case of tuberculous horseshoe kidney, he would be inclined to consider the climatic treatment in some cases with as much favor as the surgical treatment.

Case of Resection of the Rectum by the Combined Method.—Dr. WILLIAM C. LUSK presented a patient, male, fifty-five years old. He had complained of pain over the sacrum and lower abdomen for about eight months. Last August blood and pus were noticed in the stools. An examination showed a movable tumor at the upper part of the rectum, presenting the appearance of cancer. The microscopical diagnosis was malignant adenoma. The red cell count was 5,238,000; the hemoglobin was 90 per cent. On September 30, 1908, a resection of the rectum by the combined method was done. Through a median abdominal incision, the internal iliac arteries were ligated, the upper portion of the rectum and sigmoid loop were freed, and the peritoneal wound in the pelvis narrowed by sutures placed from above downward so as to draw the peritoneum as closely as possible around the descended piece of bowel. In liberating the sigmoid its meso-attachment was freed at its base, care being taken to cut the peritoneal folds first and then isolate the entering vessels and tie them without including any of the peritoneum in the ligatures. The left leaf of the peritoneum was cut higher in the iliac fossa than the right to allow stripping up of the bowel and securing the little additional descent which could thus be gained. The superior hemorrhoidal artery and one main sigmoid artery supplying the arterial arches were divided. The nutrition of the freed segment of bowel was fully preserved, so that it seemed that it would have been a perfectly feasible proposition to have interrupted the operation at this juncture and completed it at a second sitting, perhaps in this event taking the precaution to suture a fold of the splenic flexure to a small abdominal opening at the tip of the eleventh rib, which could be opened in case obstruction should supervene from kinking of the freed loop. No enlarged iliac glands could be felt. The abdominal wound was then closed. Thus far there had been no loss of blood. The patient was then turned on the left side and the rectum reached from behind through an approach designed by Dr. Lusk. A median incision was made over the lower extremity of the sacrum, crossed the right side of the coccyx, into the ischiorectal fossa to alongside the anus. The right inferior hemorrhoidal nerve was dissected. The coccyx was turned to the left. He severed the levator ani to the right of the median line and cut the attachments of the right gluteus maximus and underlying lesser sacrosciatic ligament from the side of the projecting lower extremity of the sacrum below the inferior lateral angles. He then cut across the tissues which had lain in front of the coccyx, containing the terminations of the sacral vessels. He next divided the median septum between the levatores ani and fascia propria recti, and cut the skin and muscular tissue to the left on a line with the sacrococcygeal joint. The right gluteus

maximus was split outward from the lateral sacral angle. With an osteotome he knocked off the extremity of the sacrum which projected below the level of the lateral sacral angles, and shelled off the sacral vessels from in front of their ligature. The left gluteus maximus was not split laterally, as sufficient room was gained without it. The detached fragment of the sacrum was removed at the end of the operation. Through this approach the lateral attachments of the rectum were hooked down over the finger and severed, and the whole freed segment of bowel was brought out through the posterior wound. There was some hemorrhage in constructing the approach, and considerable in stripping up a few remaining posterior median attachments of the fascia propria recti to the sacrum, which, however, soon became arrested. Before resecting the bowel a strip of plain and a strip of iodoform gauze was passed upward into the pelvis along either side of the descended bowel to shut off the peritoneal cavity. The technique of anastomosis of the bowel ends was in all essentials that method employed by Kraske. In suturing the bowel ends together he used a technique similar to that practised by Dr. George D. Stewart in suturing a skin wound. In the case shown, where the triangular space at the attachment of the mesosigmoid to the bowel came into the line of anastomosis, which was at the posterior median line, it was closed by a Maunsell stitch. All of the inside stitches were of stout iron-dyed silk. About two cm. of the stitch line posteriorly was closed from the outside by two rows of No. 1 chromic gut. A strip of iodoform gauze was placed on the right side a little above the suture line and on the left side along the suture line. Also a gauze pack was placed behind the bowel from the suture line above, to a little above the divided extremity of the sacrum. A tube drain was placed in the anal canal. The subsequent course was uneventful, excepting for the formation of a small fistula. Primary union occurred in the abdominal wound. All of the posterior wound that now remained unhealed was a small central granulating area. During a recent two weeks the patient gained nine pounds. On microscopical examination of the specimen a section of the bowel at its upper limit and at its lower limit, and lateral sections of the perirectal tissues, all showed no evidences of invasion. Also a section through the tumor where it was in relation with the bladder showed healthy tissue beyond the limit of the growth. The following observations were made: (1) No preliminary colostomy was made. (2) There was no impairment of sphincter function. (3) There was no appreciable stricture at the seat of the anastomosis. (4) The ability to methodically liberate through the abdominal route the sigmoid flexure together with its accompanying vascular arches should be another accepted argument in favor of the combined method.

Pulmonary Embolism Following Operation.—Dr. C. L. Gibson read this paper. (See page 45.)

Dr. Willy Meyer said this was a very important subject and any one who had had any experience with pulmonary embolism following operation would never forget it. Such patients might appear to be entirely well, get up from bed, and then drop dead. The principal question that confronted them at present was, How could the surgeon prevent the formation of thrombi? It was now his habit in every case in which he operated below the umbilicus to have the lower end of the bed raised and the patient instructed to move the left leg frequently. Since following this method he had not seen a case of thrombosus of the left femoral vein after aseptic operations. Dr. Meyer then exhibited Trendelenburg's instruments, which were devised for operating upon pulmonary embolism. It was to be hoped that with their use many patients will be saved who otherwise would have been lost.

Dr. Elsworth Elior said that this accident occurred more frequently after laparotomies than after any operation upon the lower extremity. He thought that the coagulation of the blood was due to the same cause as existed in the infectious fevers, such as pneumonia, typhoid fever and analogous conditions, and, therefore, he supposed it was quite possible that the coagulation of the blood might be of toxic character.

Dr. John F. Erdmann, Dr. Charles H. Peck, Dr. Aspinwall Judd and others recalled cases of pulmonary embolism following operation.

Election of Officers.— *Chairman*, Dr. Ellsworth Eliot, Jr.; *Secretary*, Dr. H. H. M. Lyle.

SECTION ON MEDICINE.

Stated Meeting, Held December 15, 1908.

Dr. Herbert S. Carter in the Chair.

Report of a Case of Addison's Disease with Autopsy.—Dr. Charles H. Lewis made this report. (See page 47.)

Dr. Rosenberg reported a case of tuberculosis in which the suprarenal glands were affected. The involvement of these glands was not suspected because there was no bronzing of the skin. At autopsy the adrenal glands were sent to Dr. Brooks for examination and he reported the case to be a typical one of Addison's disease.

Dr. Harlow Brooks said that there now was no doubt regarding the true pathology of Addison's disease; there was a slow destruction of the adrenals which might be tuberculous, syphilitic, or neoplastic. He believed that too much importance was attached to the presence of pigmentation in these cases.

Dr. Sidney V. Haas reported the case of a young man, twenty-six years old, who was very dark in color. His father had cancer of the stomach. A brother died at the age of six years from lymphosarcoma. Because of the man's color and because of the newspaper notoriety regarding bronze-skin disease at the time he saw the case, the patient was taken to Bellevue Hospital for examination. The young man was found on examination to be deeply bronzed. A careful examination of his organs revealed nothing abnormal. Several well known men in the city were consulted. One said he had Addison's disease. It was decided to watch the young man. He was placed under a tonic treatment for a time. Then prepared suprarenal capsules were given, but without any effect whatever. Then a fresh preparation was given, and in forty-eight hours he began to vomit. From this time on until his death occurred he continued to have gastrointestinal symptoms. The chief point of interest in this case was apparent onset of the symptoms of Addison's disease after the administration of the freshly prepared suprarenal extract. The patient then became asthenic and died with the characteristic symptoms of the disease.

Dr. J. Ramsey Hunt reported a case of tuberculosis of the adrenals he had had under observation a few years ago, and which was particularly interesting because it coexisted with myxedema. This patient died of a pulmonary complication, not tuberculous, but probably pneumonic. The thyroid was found to be much atrophied and, in addition, both adrenals presented an advanced degree of tuberculosis. This patient presented none of the symptoms of Addison's disease that could be recognized. There was no pigmentation and no gastrointestinal symptoms.

Dr. Wiener reported the case of a patient who died of tuberculosis, and the post-mortem revealed the characteristic changes of Addison's disease in the adrenals.

Dr. Charles H. Lewis reported another case of tuberculosis of the adrenals with very extensive involvement. Adrenalin was used for a time with marked improvement, but this was only transient. After three weeks the patient rapidly failed and died.

Toxemia of Gastrointestinal Origin; from the Labora-

tory Standpoint.—Dr. Wm. R. Williams read this paper. He said there were many persons in whom more or less obvious gastrointestinal symptoms were associated with disturbances of the general health. In the absence of other discoverable causes it was hard to escape the conviction that the primary trouble was in the alimentary canal, and that the other symptoms were merely the effect of this perversion of digestion. The gastrointestinal symptoms were those of ordinary indigestion, flatulence, feces that were too hard or too soft, that had an unusually foul odor, or were changed in color. Not infrequently there was a tendency to diarrhea. The general symptoms were headache, lack of mental vigor, vertigo, muscular weakness, anemia, loss of weight, and presumably a distinct shortening of the duration of life. Such manifestations as asthma, tetany, and even epilepsy, as well as the lesions associated with arteriosclerosis and nephritis, had been included. There was no doubt that many of these patients had excessive fermentation and putrefaction in the alimentary canal in which foodstuffs of all classes might be implicated. This association had led to diligent search for a chemical poison in the intestinal contents that could experimentally reproduce such symptoms. In this process of decomposition many substances were formed, and the question arose, were any of these substances toxic enough after absorption to justify one to regard them as the causes of the clinical conditions referred to? Also did their occurrence in excess coincide closely enough with the incidence of clinical symptoms to establish a reasonable probability of a direct causal relation? In the mouth microorganisms always abounded, and as a rule seemed to cause surprisingly little disturbance of digestion. Even in pyorrhea, where they were unusually abundant, toxic symptoms from them were hard to find. The interference with mastication was more serious, as it insured the swallowing of large masses of unchewed food. In the stomach with a normal secretion of hydrochloric acid there was little bacterial activity. If the hydrochloric acid was deficient, putrefaction might take place. Fermentation of carbohydrates sometimes occurred here even with hyperchlorhydria, although it was more common with a deficiency of the acid. Decomposition in the upper part of the small intestine was slight, with adequate secretion of the digestive juices that acted in the stomach and intestine, but with a failure of this decomposition might take place. In the lower part of the small intestine normally the lactic acid bacilli dominated and held in check the putrefactive organisms. With disturbances of secretion, or the swallowing of large pieces or excessive quantities of food, or with food of improper quality, the cultural conditions became less favorable for the lactic acid formers and more favorable for putrefactive organisms of the colon group and for the anaerobes. In the colon, putrefaction was present in the average healthy individual, but no one could affirm that harm resulted from it. With the conditions of digestion or ingestion outlined above, it might become excessive and the strict anaerobes might share more largely in its production than was the case in health. The known products of decomposition of the carbohydrates, proteins, and fats had not been proven toxic enough to explain the symptoms of gastrointestinal intoxication. Notwithstanding this the conviction could not be escaped from that in this clinical condition the primary cause did originate in the digestive tube. There might be undiscovered poisons that acted directly on the various tissues of the body, or else that first broke down the body's defense, more particularly in the liver, and then reached the other tissues and exerted their toxic action.

Toxemia of Gastrointestinal Origin; from the Clinical Standpoint.—Dr. Jacob Kaufmann read this paper. He said there was a general tendency at present to greatly overestimate the rôle which gastrointestinal toxemia played in the development of certain diseases. The fashion of the day, following the teachings of the French school, attributed to gastrointestinal intoxication various diseases of the nervous system, the circulatory system, the blood, the muscles, the skin, etc. When, however, the arguments which were usually cited to prove the intestinal autotoxic origin of most of these diseases were given it was astonishing to find how very few reliable facts gained by experimental research, by exact chemical investigation, or even by accurate clinical observation, had so far been advanced to support this theory for each case. Under the heading of toxemias of gastrointestinal origin were commonly included all intoxications which could be ascribed to the absorption of toxic substances formed in the alimentary canal by the action of digestive ferments or of bacteria. These endogenous intestinal intoxications were distinguished from the so-called exogenous intoxications, which were principally caused by the taking in of decomposed food. Together with decomposed food, products of protein putrefaction, especially of the ptomaine life, were usually ingested and thus acted as severe poisons. It seemed, however, that in a number of cases of apparent ptomaine poisoning, the severe symptoms were not caused by the action of poisons formed in the food before it was eaten, but by the effect of intestinal infection of this food by bacteria mostly of the paratyphoid type; so that these cases of apparent endogenous autointoxication were actually cases of endogenous autointoxication. Whether these and other severe pathogenic intestinal infections led to the formation within the intestinal canal of such bodies as ptomaines had not yet been definitely proven. There could be no doubt, however, that intestinal infections of this kind produced toxic substances, the absorption of which caused more or less severe systemic disturbances, although as yet no such substances had been isolated. Gastric tetany was often pointed out as one of the most striking illustrations of toxemia, caused by the absorption of toxic substances from the dilated stomach. Some years ago Dr. Kaufmann argued that gastric tetany was caused by an impoverishment of chlorides in the system, which was brought on through the constant loss by vomiting and lavage of great quantities of chloride with the highly acid secretion. This theory, that the attacks were caused by a loss of a constituent necessary to the intermediary metabolism, and not by the toxic effect of a substance absorbed from the stomach, was well corroborated by experiments. In some conditions it was the resemblance of the symptoms to those brought on by the known effect of poisons which justified the assumption of intestinal intoxication. In no disease had this been demonstrated with more clearness than in certain cases of pernicious anemia. In other conditions which were usually attributed to intestinal intoxication, the characteristic symptoms were not such as to suggest intestinal intoxication as the most probable cause for their development. In asthma dyspepticum, for instance, the direct mechanical effect of the gas-distended viscera, usually found in these cases, and the effect of nervous relaxation offered a much more plausible explanation. The fact that the attacks occurred in connection with digestive disturbances and disappeared with their improvement did not throw any light upon their assumed toxic character, and the same might be said of numerous other conditions looked upon as intestinal toxemias, particularly diseases of the nervous and circulatory system, the skin, etc. He said he was far from underestimating the importance of digestive disturbances in the development of diseases of other organs. For some diseases there was a rational explanation other than the autotoxic which made one understand the causal connection between digestive and other systemic diseases. The present tendency to consider these diseases as principally caused by intestinal intoxication was not justified. The products of fermentation of carbohydrates, the acids in the alimentary canal, were

on the whole harmless; but if increased in quantity they formed a local irritant, causing vomiting or diarrhea. Lactic acid with bacterial gastric fermentation seemed to be well tolerated even when produced in large quantities. Much weight was attributed to the products of intestinal putrefaction of proteins, which were chiefly held responsible for intestinal toxemia. Dr. Kaufmann then considered the following questions: (1) What information did one obtain from the finding of increased intestinal putrefaction in regard to intestinal intoxication? (2) How far was one justified in interpreting an excess of indican in the urine as a sign of intestinal intoxication? The different possibilities were considered. Increased intestinal putrefaction might cause an increase of the known normal products of putrefaction, and it might lead to the formation of other new products of toxic character. It was often assumed that with increased intestinal putrefaction, new substances were formed, which might possibly act as toxins. As long as such hypothetical substances had been demonstrated, it was of questionable value to estimate their presence and quantity by measuring the degree of intestinal putrefaction in general. The mere presence of such substances in the feces would not mean anything in regard to their toxic effect upon the system, because they might be detoxicated after absorption. All efforts, however, to find such enterotoxins in the urine had so far failed. Especially the determination of the so-called urotoxic coefficient could not be considered a reliable method of diagnosing the presence of enterotoxins in the urine and still less of measuring their quantity. With regard to the known products of gastrointestinal putrefaction, it must be said that, according to present knowledge, only few were toxic to any considerable degree, and these were produced in too small quantities to cause any appreciable effect. Only one product of protein putrefaction in the intestine, hydrogen sulphide, had been demonstrated that might cause symptoms of intoxication. An excess of indican in the urine was not sufficient to diagnose intestinal toxemia. In neurasthenia there was an increased susceptibility to exogenous toxins like alcohol and tobacco. It was assumed that a like increased susceptibility existed for the toxic effect of products of intestinal putrefaction, which under ordinary circumstances were well tolerated by the system. Taking this for the correct view, it would only show that the toxic effect of intestinal products might aggravate the neurasthenic condition. But it could not be taken as an argument for the claim of some writers, that intestinal intoxication was an important primary cause of neurasthenia. Heredity, worry, overwork, etc., he considered primary causes of neurasthenia. Since digestive disturbances were often associated with neurasthenia, the effect of increased intestinal putrefaction might prove deleterious in creating a vicious circle. Among the symptoms often quoted as characteristic of intestinal intoxication he mentioned albuminuria. The kidneys were very susceptible to poisons and albuminuria occurred regularly when poisons were passed through the kidneys. From his own observations he said he had come to the conclusion that in one distinct group of digestive disturbances, albuminuria was caused by increased acidity of the urine, with and without uric acid or oxalic acid sediment. When in these cases alkalis, especially preparations of magnesia, were administered in such quantities that the urine became slightly alkaline, the albumin disappeared, to recover again with renewed, increased acidity. In these cases, therefore, albuminuria was not caused by the direct action of enterotoxins on the kidney, but by the effect of the products of disturbed metabolism. This led to a different aspect of toxemias connected with diseases of the digestive tract. Gastrointestinal disorders often interfered with the activity of the liver, thereby disturbing the normal process of metabolism. The results of disturbed metabolism, symptoms of the uric acid diathesis, the development of diseases of the kidneys, the arteries, heart, etc., were often described as caused by the action of toxins of intestinal origin. If by the term gastrointestinal toxemia was meant the intoxication caused by the action of substances absorbed from the alimentary canal, then these were not cases of gastrointestinal, but of metabolic toxemia. It was necessary to distinguish strictly between gastrointestinal and metabolic toxemias, especially at present, when Metchnikoff's ideas had taken such a hold on the laity and profession, and when it was almost taken for granted that the so-called antifermentative treatment of digestive disorders was the most important and the most effective way of dealing with chronic systemic diseases. Effective treatment of gastrointestinal disturbances was certainly of great importance in systemic diseases; but he doubted very much whether this difficult task could be accomplished when the plan of treatment was based on the theory that the action of enterotoxins was at the bottom of it all. The fascinating theory of gastrointestinal toxemia was, in most instances, still very much in need of support by objective facts. If they wished to gain more evidence and to clear up the many questions connected with this theory, he said they must show a more critical attitude than was generally displayed at present.

Dr. T. W. Hastings said that the blood changes which might occur in intestinal intoxication were those which occurred, as a rule, in long continued or chronic intestinal intoxications. Sulphhemoglobinuria resulted from disturbances in absorption. So far as the changes in the blood serum were concerned he was not familiar with them; but the changes in the corpuscular elements had been described by many writers. The changes occurred mainly in the red cells. Clinically these changes could be separated into two classes of cases which could be substantiated by a blood analysis. The rarest cases were the most interesting, where there were no marked disturbances in the blood, the red cells, or the blood as a total mass, but the change occurred in the blood pigment producing sulphhemoglobinuria. He drew attention to the distinguishing of sulphhemoglobinuria from cyanosis and to the work West and Clark had done on this. Another set of changes was to be found in the anemias, particularly in pernicious anemia, and Hunter had already described intestinal intoxication as a cause of pernicious anemia in 1888. These changes were not due to the absorption of putrefactive products in the intestines, but to infection of the intestinal wall. Addison in 1855 said that this disease was an infectious one, in which there was an excessive hemolysis. Herter had thrown considerable light upon this subject. Clinically the main reason for thinking this disease was toxic in origin was based upon finding so many neurotoxic disturbances in certain types of pernicious anemia. Secondary chlorotic anemias were produced. The one blood change which was commonly met with was the occurrence of mild secondary chlorotic anemia. In the acute cases of intestinal intoxication the diagnosis was so uncertain that it was difficult to state just what the blood changes were.

Dr. J. C. Roper said the old values that were placed upon the changes in the urine had been destroyed by the discoveries of Follin, and especially in regard to the nitrogen ratios. Dr. Conner and he had done much work recently in a study of the excretion of urobilin; he had found that in pneumonia cases, when it was liable to demonstrate the presence of urobilin in the blood, at autopsy considerable changes were found in the liver. It seemed to them possible that the excretion of urobilin with bile in the blood might be due to a diminished power on the part of the liver and might in fact be an exhibition of failing power.

Dr. J. Ramsey Hunt said that gastrointestinal intoxications among neurologists were considered as playing a definite rôle, or a causative rôle, in the production of a

large group of functional nervous diseases, both the psychoses and the neuroses. But they, in turn, might cause gastrointestinal disturbances, thus producing a vicious circle. Dr. Kaufmann had mentioned a very important point, that there was a group of cases abnormally susceptible to intoxications of any kind. With regard to epilepsy it was a common experience to see fits bearing a certain relation to intestinal disturbances and especially constipation. It was also a common observation that the pains of locomotor ataxia bore a certain relationship to the accumulation of feces in constipation. But in these cases, as well as in epilepsy, the causal factor might be mechanical as well as toxic. There was, however, one affection of the nervous system which always impressed him forcibly as bearing a close relation to intestinal intoxication, *i.e.* disturbances of the spinal cord, the so-called combined scleroses of the spinal cord. These might be associated with the anemias. They were regarded as toxic in origin, and he had seen cases in which degenerative changes in the spinal cord preceded the signs of anemia by a definite period of time. He was very hopeful regarding this group of organic nervous diseases which had a relation to intestinal intoxication. In poliomyelitis occurring in children, some had sought for microorganisms in the gastrointestinal tract, but nothing was found there to support any theory that the microorganism had any casual bearing on the disease.

Dr. L. F. Bishop believed that a practical clinical aid came to the general practitioner in his estimation of indican in the urine, giving him information as to the amount of gastrointestinal disturbance present. Dr. Bishop said he had studied over ten thousand specimens of urine and he was struck by the frequent association of indicanuria and albuminuria. When there was a marked indicanuria there often appeared a persistent albuminuria, and very often there was associated the presence of hyaline and sometimes granular casts. Cardiac symptoms were associated as a rule. It was necessary to revise the ancient theory that the cardiac neuroses or disturbances associated with gastrointestinal symptoms were reflex in origin through the nervous system. One thing that had impressed him very much was the chemical connection between the stomach and the heart in these cases; a patient with gastroenteric symptoms would have a weak and intermittent heart, palpitation, etc., and it would appear to be a real cardiac condition, but the cardiac condition was the result of the intestinal intoxication and the absorption of the chemical products.

Officers Elected.—*Chairman*, Dr. Fred P. Solley; *Secretary*, Dr. C. N. B. Camac.

College of Physicians of Philadelphia.

At a stated meeting held December 2, Dr. Charles Lester Leonard presented a communication entitled "Röntgenographic Studies of Peristalsis: The Relation of Waveform to Function." He demonstrated by means of lantern pictures the course of bismuth-emulsions through the esophagus, the stomach, and the bowel. Dr. Wm. C. Spiller read a paper entitled "Circumscribed Serous Spinal Meningitis: A Little-Recognized Disorder Amenable to Surgical Treatment." He referred to the rarity of this disorder, which occurs as a cystic collection of fluid within the spinal dura and gives rise to symptoms of tumor. But few cases of the affection have been put on record, and only one in which successful operation was performed. This case was reported more than six years ago by Drs. Musser, Martin, and Spiller, and the patient has survived the removal of the cyst until the present time. Drs. John Speese and Edward H. Goodman presented a paper entitled "Experimental Studies of the Pancreatic Reaction of Cammidge." They were able to demonstrate this reaction in the urine from dogs in which pancreatitis was excited by injection of olive oil in the pancreatic duct.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 2, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	361	172
Diphtheria	392	36
Measles	363	16
Scarlet Fever	296	19
Smallpox	—	—
Varicella	105	—
Typhoid Fever	48	12
Whooping Cough	24	3
Cerebrospinal Meningitis	6	4
Malarial Fever	—	—
Totals	1595	262

Suppurative Lesions Developed Within the Fetal Membranes.—A. Fruhinsholz describes a case of abortion in which the immediate cause of the detachment of the ovum was a collection of pus containing pneumococci that was found between the amnion and the chorion. The possible origins of this purulent infection are these: Infection of the uterine cavity before conception; infection from the vagina before the union of the layers of membranes; infection resulting from attempts at abortion; localization in the uterus of matastatic deposits arising from a grippal contamination, and reaching the uterus by way of the blood. The author ends with an account of ten similar cases found in literature.—*Annales de Gynécologie et d'Obstetrique.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending January 1, 1909:

DARWINISM AND MALARIA.

By R. G. ECCLES, M.D.,
BROOKLYN, N. Y.

Malaria and Darwinism—historically considered are quite closely interlinked. Most Darwinians forget that it was not Darwin, but an American physician, who first gave to the world what we call Darwinism—Natural Selection as a means of explaining biological adaptations. The principle itself was announced by Empedocles, 2,000 years ago, but not used in the modern way—as Darwin used it. Professor Darwin himself tells us that the honor of having first used it as he did belongs to Dr. W. C. Wells of Charleston, S. C., who, in 1813, communicated a paper to the Royal Society of Great Britain entitled "An Account of a White Female, part of whose skin resembles a Negro," in which such a use was made of it.[1] In this paper he sought to explain how the negro came by a black skin as a survival in the struggle with malaria and other tropical diseases. Had he worked his theory out as completely as Darwin did, America would have won the prestige which Britain secured by the publication of the "Origin of Species." Darwin tells us that Wells, "after remarking that negroes and mulattoes enjoy an immunity from certain tropical diseases, he observes, firstly, that all animals tend to vary in some degree, and, secondly, that agriculturists improve their domestic animals by selection; and then, he adds, but what is done in this latter case by art seems to be done with equal efficacy, though more slowly by Nature, in the formation of varieties of mankind, fitted for the country which they inhabit. Of the accidental varieties of man, which would occur among the first few and scattered inhabitants of the middle region of Africa, some would be better fitted than others to bear the diseases of the country. This race would consequently multiply while the others would decrease—not only from their inability to sustain the attacks of disease, but from their incapacity of contending with their more vigorous neighbors. The color of this vigorous race, I take for granted, from what has been already said, would be dark. But, the same disposition to form varieties still existing, a darker and a darker race would in the course of time occur."[2] The tropical diseases familiar to Wells and toward which he had observed the negro's relative immunity were no doubt malaria and yellow fever. The harvest gathered by death through each is great, but that from malaria is much the greater. The article "Malaria" in the "Encyclopedia Britannica," tells us that this disease "has been estimated to produce one-half of the entire mortality of the human race; and, inasmuch as it is the most frequent cause of sickness and death in those parts of the globe that are most densely populated, the estimate may be taken as at least rhetorically correct."[3] So deep an impression did the havoc that malaria wrought have upon some of the older writers that it was declared to be "a destroying angel" sent to earth to keep man within proper bounds.[4] A few years ago Dr. Patrick Manson stated that no less than five million British subjects annually die of it,[5] while Professor Celli asserted that in Italy, two million persons are attacked and fifteen thousand killed by it each year.[6] If we include the world as a whole malaria seems to be, for the human race, the chief instrument of Natural Selection. In some parts of the earth it has no influence and in others its influence is but slight. Until quite recently the universal belief of medical men was that it was due to bad air, and hence the title malaria. A similar belief was entertained regarding yellow fever and it is not many years since a special committee of the New York Medical Society reported that yellow fever may be produced in any country by "pestilential effluvia."[7] This old theory is thoroughly non-Darwinian, inasmuch as, if true, there could have been no survival of any fitness. A condition of bad air or swamp effluvia could be no modern thing if our geological record is reliable. We ought to have become entirely indifferent to it long ago, through the deaths of the unadapted. The fact that we are not is evidence that no sooner are we immune than it checkmates our immunity by some change in itself. But this indicates that it is alive and struggling for existence. The first theory of malaria that agreed with Darwinian principles was the mosquito one. It presented to our understanding a struggle of living thing with living thing even when the Laveran parasite was unknown and the mosquito was only part of the correct explanation. The first presentation of this theory was made in 1807—six years before Dr. Wells propounded his theory of Natural Selection. It is now, however, over a century since Dr. John Crawford of Baltimore, Md., gave to the world his mosquito theory of malaria. Instead of meeting with enthusiastic acceptance, as a new clue worth testing, it was allowed to go to slumber in unmerited neglect. No harm could have come from its discussion and trial other than that it would have upset the inherited, factless conception of a malaria. It is easy to understand why Dr. Wells' theory was allowed to go to slumber for close on forty years. On it hung no such issues of life and death. Against it was the whole influence of nineteenth century theology. There was no body of men directly interested, for the sake of themselves, their families, and their suffering patients, in getting the proof of its truth. Not so Crawford's theory. Its neglect is astonishing. Nothing more was heard of it till 1848 when Dr. Josiah Nott of Mobile, Ala., took it up again after it had slept forty-one years. Out of an entire generation of medical men only one single soul showed any interest in it. It does seem as if

after so long a slumber a host of interested reasoners should have arisen to give it a trial. It was neither a chimera of insanity nor a mystic mouthing of ignorance but a rational hypothesis capable of putting life into a lot of otherwise unexplainable facts. That Nott's efforts met the same chilling neglect as did those of Crawford proves that there is something radically wrong in modern methods of education. For another thirty-five years no one paid the slightest heed to this priceless theory. In 1883 Dr. A. F. A. King of Washington, D. C., came like a third John the Baptist, crying in the wilderness of medical nonappreciation. Through the *Popular Science Monthly* he sought a hearing.[8] The time seemed opportune. Just three years before Dr. A. Laveran, in the Military Hospital at Constantine, Algeria, Africa, had discovered the malarial parasite in the blood of malarial patients. His discovery had been confirmed at Rome and in other places.[9] Everything seemed ripe for the adoption of so promising a working hypothesis—everything but the deathly indifference of medical men. Suggestive as the situation was, King's efforts proved as unavailing as did those of Crawford and Nott. The theory touched no sympathetic chord in the minds of those who read the gathered evidences of its truth. It did not occur to any of them to ask how Laveran's parasite could get into the blood of malarial patients from the swampy regions in which malaria had long been known to make its home. That would have been theorizing and most of our teachers were opposed to theories. Old and popular theories could be tolerated but no new ones were wanted. The Encyclopedia Britannica, in an edition that followed the publication of King's article in the *Popular Science Monthly,* describes the popular theories of malaria but makes no mention of the mosquito one.

Eleven more years passed, after the third attempt to stir up interest, when Dr. Patrick Manson, while making a study of Laveran's organism, discovered in its structure evidence that it must be insect borne. In a succinct statement of Manson's reasons for his belief, written by Major Ronald Ross for the *International Medical Annual,* we read that "fixing his attention on the gametocytes (the form assumed by the organism before it develops males and females) and on the fact that they emit the motile filaments only after the blood is taken from the host, he concluded that the emission of the filaments is a natural, organic process in the history of the parasite, meant for its further development within some suctorial insect. The sporocytes (*i. e.* the spores that end the cycle in the mosquito and begin the non-sexual cycle in man), he said, continue the life of the parasites within the first host (men, birds, and so on); the gametocytes continue it within a second host, the suctorial insect. He thought that the motile filaments are merely flagellated spores which are produced from the gametocytes just as the ordinary spores are produced from the sporocytes, the former attacking and living in the tissue-cells of the second host just as the latter attack and live in the fresh blood-corpuscles of the first host. It was evident at once that the suctorial insect could be no other than the mosquito."[10] When Manson drew this conclusion it was fortunate for him, and for medical science, that he found in Major Ronald Ross a willing listener, a man of proper training, and one that took interest in the practical testing of such an idea. It was likewise part of the fortunate combination that Ross was situated in an environment—India—where the theory could be put to a proper test. But for such a favorable combination we fear that the theory might still be awaiting someone to prove its truthfulness. Major Ross's work ended in perfect success and in 1898 the medical world was startled by his report. Great Britain, through him, had won an honor that ought to have come to the United States. To my mind the facts collected by Dr. King are unexplainable on any other conceivable theory than the mosquito one. They are, of course, of a wholly different character from those given by Dr. Manson. It has been said that King's facts "afford no more than a weak probability in favor of the great theory" and that "it is certainly to Manson that we owe the real mosquito theory of malaria."[11] We surmise that the entire array of facts submitted by King had not been read by the writer of the words here quoted. To be told that Manson's "was not the weak hypothesis founded on doubtful coincidences and analogies which had hitherto held the field, but a true scientific induction,"[12] is far from fair to the American writer. Without intending, in the slightest degree, to detract from the honorably won glory of Sir Patrick Manson, nor from the brilliancy of the triumph of Major Ronald Ross, we would like to have every fair-minded reader of this article try to bring King's facts into any other interpretation than that which he gave them. Manson has been honored with knighthood, with medals, with degrees, and with other honors. He deserves every one of them. King, the American, is treated with neglect notwithstanding Ross's proof that the theory so ably presented, in 1883, was the right one. The facts then collected pointed out that both mosquitos and malaria (*a*) occupy the same regions, (*b*) are hindered from reaching their victims by screens, coverings, or nettings, (*c*) develop at a common temperature (about 60° F.), (*d*) disappear at a common temperature (about 32° F.), (*e*) increase their ravages progressively toward the equator, (*f*) are caught by dense foliage when the wind blows from swamps toward such foliage, (*g*) are carried to the same distances by the wind, (*h*) cling to low, damp regions in calm weather, (*i*) keep near the ground save exceptionally, (*j*) steadily disappear as a region gets thickly settled, (*k*) appear in the freshly dug or excavated ground of wet regions, (*l*) are most pronouncedly active after sundown, (*m*) attack out-of-door sleepers more frequently than in-door sleepers, (*n*) penetrate but short distances into large cities, (*o*) are at their worst in summer and autumn, (*p*) are checked in their distribution by high walls, (*q*) are rendered more pernicious by cutting marsh shrubbery, (*r*) travel only with the wind, (*s*) attack those lying down more than those up and moving, (*t*) travel but short distances from swamps except on rare occasions, (*u*) are inhibited by smoky fires, and (*v*) are bred by tanks, millponds, and reservoirs.[13] This simply means that the habits of the mosquito parallel the peculiarities of malarial attacks down to the most minute details obtainable by ordinary observation. Was this a weak hypothesis? Are these doubtful coincidences and analogies? Either this complex parallelism is proof of a miracle or it means that mosquito and malaria were necessary parts of one another. It is far too complex and too perfect to be explainable on any theory of coincidence. Why was it ignored? Let the reader pause and ask himself what would have been the result if the far weaker and less coherent mosquito theory of yellow fever had continued to be ignored in the same way. Where would have been our triumphs in

Cuba and Panama? Had Americans been ready to do for Nott and King what Low and Sambon did for Manson and Ross—simply give the theory an honest test—the glory of the proof would have been ours instead of Britain's.[14] But, alas, so many of our doctors have no use for theories.

In the writings of both King and Nott yellow fever was coupled with malaria as being mosquito borne. In this phase of their theory they had an enthusiastic supporter in Dr. Charles Finlay, of Havana, Cuba. For twenty years the latter gentleman had striven to convince his stubborn, or indifferent fellow practitioners that if they would get rid of their swamps and mosquitos they would get rid of their yellow fever. His efforts were unavailing. Not until Ross made his discovery was there sufficient faith on the American continent to give the matter a fair trial. On learning of his work and its success the instinct of imitation, combined with the fact that his triumph as a theory chaser had severely scotched antitheory sentiment, brought us to our senses. The members of the American Yellow Fever Commission, composed of Drs. Reed, Carroll, Agramonte, and Lazear, after having obeyed instructions in trying to run down Sanarelli's *Bacillus icteroides*, grasped at the Nott-Finlay theory and won the proudest success that has ever come to American medicine.[15] Well has Tyndall said: "A perfect theory gives dominion over natural facts; and even an assumption which can only partially stand the test of comparison with facts may be of eminent use in enabling us to connect and classify groups of phenomena."[16] Haeckel, too, is of the same way of thinking for he tells us that "A weak hypothesis is always better than none. We must therefore protest against the foolish dread of hypotheses which is urged against our phylogenetic methods by the representatives of the exact and descriptive sciences. This shrinking from hypotheses often hides a defective knowledge of other sciences, an incapacity for synthetic thought, and a feeble sense of causality."[17] One of the most recent statements of scientific men regarding the benefit of theory is that of Prof. H. A. Bumstead of Yale, who declares that "A marked characteristic of modern physics is the free and fearless use of hypotheses—a use which would have been regarded as dangerous, or at least unscrupulous, in the days before we had been taught by the example of great masters like Faraday, Kelvin, and Maxwell, that hypotheses were the most useful of all instruments of research."[18] How long is it going to take some of our medical teachers to learn that it is a duty they owe to the world to stop denouncing and take to searching for all the newest theories they can find in order to promote instead of hindering discovery? The sooner they do so the better, for there can be little doubt of the fact that we are now facing a vista in the deep forest of medical research that promises greater wonders than the past has dreamt of. Now it is theory, but soon it will be fact, if these men can be made to hold back their discouraging efforts. Sir Patrick Manson recently took a medical audience into this new wonderland of protozoological development. He said: "One can readily understand how an animal, originally free, can adapt itself to parasitic life on another animal, but it is very difficult at first sight to explain how it can accustom itself to life in two absolutely different hosts so far removed from each other, zoologically, as man and a mosquito; and, further, that both man and mosquito are essential for its welfare; and, moreover, that in one host —in this case the vertebrate—the parasite has an asexual life and in the other host—the insect—a sexual life. How by any recognized principle of evolution can a life so complicated be attained or explained? I would with great diffidence and without entering on detail submit the following hypothesis. Vertebrates, arthropods, molluscs, helminths, protozoa, have all of them sprung from a common ancestor, or, if not from one common ancestor, from similar ancestors. Very early in the growth of the family tree a certain originally free organism became at first intermittingly, then finally and permanently, parasitic on another organism. In time a definite host and parasite relationship was established between the two. From the original host varieties, species, genera, and so on were gradually evolved. Concurrently with this evolution in the host-parasite, just as its host had done, adapting itself to its changing environment, evolved new varieties, species, genera, etc. In the course of these concurring evolutionary processes there came a time when, say, the insect and vertebrate strains began to diverge. A certain organism was parasitic on the common insect-vertebrate ancestor. The process of evolution in this host ancestor being necessarily very gradual, the parasite—as is the case with many existing parasites—was capable of adapting itself to the closely related varieties of the host, among others to the insect-resulting strain and to the vertebrate-resulting strain. Divergence in these host-strains continuing, varieties became species, species genera, and so on, until insect and vertebrate, as they exist at the present day, were evolved. In the early stages of the evolutionary process the parasite could live in either vertebrate strain or insect strain of host indifferently, but there came a time when it was often more to the advantage of the parasite to pass its sexual life in the ancestral insect strain. In the process of evolution this at first more or less accidental habit—I can hardly apply the expression 'optional habit' to a parasite—became fixed and has been transmitted so that now the sexual life of the malaria parasite is passed in the mosquito, its asexual life in man. This is my explanation of the double life, if I may so describe it, of so many and so widely separated parasites, including protozoa, nematodes, trematodes, and cestodes. I can explain it in no other way; the explanation I offer seems to harmonize the facts and to conform to the doctrine of evolution."[19]

According to the view which Manson has here expressed every step in evolution from invertebrate creatures to vertebrate fish, beasts, birds, and men—their phylogeny—has been paralleled by an evolution within them of different kinds of infesting parasites. Through myriads of ages these permanent parasites have injured and sickened, killed and maimed every form of host that nature has developed, while adhering to their parasitic proclivities with as much persistence as the higher forms adhered to life. They have, according to this, never ceased from being parasites and descendants of parasites through the countless millenniums that intervene between us and our remote jelly-fish ancestors. While we know that, at present, some of the parasites are apparently but slightly if at all harmful, yet the supposition will not down that given other conditions they might become quite dangerous and there is the possibility that before the balanced condition came they may have been seriously dangerous. While some zoologists might demur at the extension of the malarial type of para-

sitism back to the beginnings of metazoic life most of them agree with Manson as to the very great antiquity of parasitism. Indeed so thoroughly fixed in the minds of scientific men is this belief that some of them use it as a means of estimating the relative antiquities of mammalian species and genera. Of two species of wild animals, the relative antiquities of which cannot be settled by their structures, von Jhering has used the permanent parasites which they carry as his guide.[20] But it is more with malarial parasitism than parasitism in general that this paper has to deal. The problem which Manson raises, in connection with the former, is an exceedingly important one. It is also one which is likely to cause a good deal of lively discussion before a consensus of opinion can be reached concerning it. We are now quite certain that three, and perhaps four, species of plasmodium have succeeded in getting into human blood to be swung shuttle-like from man to mosquito and from mosquito to man in what appears to be an unending rhythm. The old question in Froude's fable of the wise owl, regarding which was the first, the owl or the egg, here again confronts us in a slightly altered form. As the owl came out of the egg and the egg came out of the owl, in never ending succession, so each parasite of malaria shuttles from mosquito to man and from man to mosquito, unendingly. The query in John Hay's poem of "Little Breeches," when the little chap was found among the lambs, is quite appropriate as regards the malarial organism. "How did it get there?" We might reply, interrogatively, "Angels?" but the answer would be as unsatisfactory in the one instance as in the other. So far as can be seen this shuttle game has been going on everlastingly. If we pause to earnestly ask ourselves how it could possibly have begun we are overwhelmed with the difficulties of the question. It is apparently insoluble. Some of us will be content to pronounce it a mystery and let it rest at that. A few may look upon the raising of such a question as a piece of impious impertinence. The Darwinian will not hesitate to attack it as a survival of conditions of fitness and hope in the record of evolution to find evidences of his deduction. It is too important a problem for us to play the philosophic coward with. Attached to its solution there is too much of weal or woe to human-kind for us to let it alone. Viewed as a result of natural law there is no reason why, by induction, we should not be able to get at its cause and meaning. If we must accept it as a prearranged plan of creation we will have to revise our ethical conceptions in order to reconcile ourselves to what surely looks quite like malevolence toward man. Man seems to have been made for the plasmodium and not the plasmodium for man. No matter how we view it, however, the conviction is sure to grow, if we think of it at all, that this condition is one of great antiquity. To men not hemmed in by known scientific facts numerous plausible explanations might arise that would make it appear as if, possibly, recent. The less one knows about a subject the less imagination is restricted in conjuring up theories as explanations. Child and savage have minds so blank regarding biological facts that either might be led to believe that frogs could develop on dry land without a tadpole stage or human ova grow into babies by being deposited in a mudpuddle. To know the facts about the plasmodia of malaria is to lose the pleasure of indulging in child-like theories concerning them. These facts will not allow us, for instance, to conceive that at some recent period an infected mosquito from a swamp brought the plasmodium from there and, for a first time, injected it into man where it developed. The life of the organism is known to be such that that would be a miracle. We could as reasonably think of babies growing out of mud or evolving from a cabbage. The inherent nature of the parasite is such that it is bound as closely to its conditions of life—under the penalty of death for deviating therefrom—as we are.

We are told by Prof. E. A. Minchin, Protozoologist of the University of London, that "the life cycle of the malarial parasite is now thoroughly known in all its features" and, likewise, that it is "sufficiently well established that mosquitos neither come into the world infected with these parasites, nor acquire them in any other way but from the blood of their prey."[21] Years of careful search have failed to discover the slightest sign of any other way in which these organisms could reach man than through a mosquito and, what is still more to the point, their natures are such that they give no hint of any possibility of their being able to live outside one or other of their two hosts. The sexually produced spores that reach man from the mosquito—the sporozoites—are never produced in man or any other known animal than the mosquito. The asexually produced forms that reach the mosquito from man—the gametocytes or sporonts—are never produced in the mosquito. After malarial blood is drawn "formation of gametes (*i.e.* male and female forms that are produced by the gametocytes) commences immediately, the chief stimulus to this development being apparently the lowering of temperature, since the whole process can be observed under the microscope in blood drawn fresh from the body."[22] These plasmodium gametes conjugate only within the body of the mosquito. There they produce, by such conjugation, motile, worm-like forms—the oökinetes—and these are not found in the blood of man or other creature than the mosquito. When formed "the oökinete by its own activity bores through the epithelial lining of the stomach of the mosquito"[23] in order to reach its resting place for further development. It is so much at home within the mosquito that it does not fail in guiding itself to the proper part of the body of this host. Each round in the life of the parasite in man ends up by forming a rosette-like cluster of small bodies that breaks up into what are known as merozoites. Such clusters never appear in the mosquito. Each merozoite starts once more the human cycle which goes on through its successive stages until the rosette-like clusters again appear to once more break up into merozoites. These merozoites once more start new generations within man so that in this way the round of multiplication goes on at a rapid rate. This round has received the name schizogony because of the increase in the number of the organisms being due to a cleaving or dividing-up process. In the course of time this method of multiplying by cleavage slows down and finally comes to an end so that "we know unless it is again passed through a mosquito that it dies out spontaneously in every instance and in a space of time something less than three years."[24] The propogative process, which occurs only in the mosquito, is due to the conjugating of males and females and ends up in a supply of what are called sporozoites. It is technically known as sporogony. The essential fact in connection with our argument is the irreversibility of these so far as hots. Sporogony cannot

take place in man nor schizogony in the mosquito. For the parasite to miss either would mean certain extirpation. As well expect the region of a pond to be stocked with frogs after all tadpoles had been killed or to produce tadpoles after all the frogs had been destroyed. If men could be kept out of the way of mosquitos or mosquitos out of the way of men the earthly existence of all malarial parasites, of the kinds that infect men, would abruptly terminate. They cannot maintain their existence without both hosts. We and the mosquitos seem as if created for the express benefit of these parasites. The combination is a wonderful one and—for the plasmodium—all that could be desired. If evolution is true, there ought to be some footprints showing how so remarkable an adaptation came into being. Before going in search of such facts let us diverge a moment in order to clear up a point that might be somewhat foggy.

In modern zoological and botanical classification all organisms are listed, as nearly as possible, in relation to structural affinities. In consulting such classifications we are prone to forget that wherever we find the name of a given organism placed we are able from there to trace its phylogenetic geneology. Its race relationship, through the geological ages of the past, is told by the place in which we find the name. Why this is so can be seen from the following statement of Darwin: "All organic beings have been formed on two great laws—Unity of Type, and Conditions of Existence. By unity of type is meant that fundamental agreement in structure which we see in organic beings of the same class, and which is quite independent of their habits of life. On my theory unity of type is explained by unity of descent."[25] Prof. H. E. Crampton of Columbia University, commenting upon Linnæus' view of classification, and comparing it with the modern—Darwinian—one, says: "But classification was to Linnæus an end in itself, he could not see that it was but a means to the larger end of understanding and expressing evolutionary relationships—that resemblance means consanguinity."[26] Every classified animal is thus taken to be, through direct, lineal descent, a more or less remote blood relative. The animal kingdom is like a tree with diverging branches. The largest branches are known as phyla, branches of these are called classes, and subsequent smaller and smaller branches are orders, families, genera, species, and varieties, respectively. Animals of the same variety are very near of kin. Animals of the same species are likewise near of kin but not so near as when of the same variety. Animals of the same genera but of a different species may be quite remote from each other in kinship but not so remote as if of different genera. When we find all dogs classified as *Canis familiaris*, all wolves as *Canis lupus*, and all jackals as *Canis aureus* it means that we have here three species of the genus Canis. While not as near to each other in blood relationship as the varieties of dogs known as setters, hounds, or Newfoundlands, they are still quite near of kin. The fox belongs to the genus Vulpus and both Vulpus and Canis are genera of the family Canidæ. While, then, fox and dog are genealogical kin their degree of consanguinity, according to this classification, must be less than that of wolf and dog. The family Canidæ belongs within the order Feræ—an order that includes all ferocious animals or carnivora. Felidæ, Ursidæ, and other families belong in this order with Canidæ. In the family Felidæ is the genus Felis, the best known species of which is *Felis domesticus*—the common cat. In the family Ursidæ is the genus Ursus with its well known species—*Ursus horribilis*—the grizzly bear. In this way we find the relationship separating wider and wider apart. The order Feræ belongs in the class Mammalia, which embraces every kind of animal that suckles its young. To this class man, himself—*Homo sapiens*—belongs. Next comes the phylum Vertebrata which includes every animal having a backbone. To this immense branch upon the tree of life there are attached many classes, orders, families, etc. Until very recently medical science had little or nothing to do with the phylum Protozoa. Now it begins to loom up before us as if about to be of superlative importance. Its branches, subbranches, sub-subbranches, etc., are likely to very soon become common knowledge among physicians. To-day few know anything about them. Its divisions are made upon the same general plan as that just outlined of the Vertebrata, and kinship within them is determined in the same manner. It is to this that the reader will now have his attention directed. On it hangs the truth or nontruth of Sir Patrick Manson's words which we have quoted. On it hangs—so far as my limited vision can now see—the means of acquiring information regarding the origin of our present powers of resisting disease. One class of the phylum—the Sporozoa—is, probably, the most remarkable and the one likely to attract medical men most. We must know the kinship existing among the organisms which it contains in order, if possible, to discover how the mosquito-human shuttling began.

In Allbutt's "System of Medicine" we are told by Prof. Minchin that "*Plasmodium* Marchiafava and Celli . . . comprises the various malarial parasites of mammals and birds, the agent of transmission being in all known cases a gnat or mosquito of the dipterous family *Culicidæ*. The trophozoite is always of amœboid form, and is intracorpuscular during the whole trophic phase. A characteristic feature of all malarial parasites is the production of an excreted pigment termed *melanin*, derived from the hemoglobin of the blood."[27] From this we learn that the genus Plasmodium was first named by Professors Marchiafava and Celli, that all of its species are carried by mosquitos, that in the form in which it is actively engaged in absorbing nourishment (the trophozoite form) it is always amœboid as distinct from some related organisms that are not amœboid in this stage, that it makes its home during the nourishment absorbing phase within the red blood cell, and that no other genus of the order to which Plasmodium belongs so distinctively produces melanin. The generally recognized and named species of Plasmodium are:

1. *Plasmodium vivax*, found in all cases of tertian malaria.

2. *Plasmodium malariæ*, found only in cases of quartan malaria.

3. *Plasmodium immaculatum*, found only in pernicious malaria.

4. *Plasmodium kochi*, found in malaria-infected monkeys.

5. *Plasmodium præcox*, found in malaria-infected birds.[28]

Besides these are a number of unnamed species found in bats, other mammals, and even reptiles. There is still considerable dispute concerning the naming of malarial parasites. *Plasmodium immaculatum* is placed by some authorities in a genus named *Laverania* while still others place *Plasmodium præ-*

cox in the genus *Hæmoproteus*. The distinguishing features of the various species are given by Prof. Minchin in these words: "The schizonts are distinguished by trifling differences of pigmentation in the three (human) species, and also by variations in the process of sporulation. In the quartan parasites the rosettes have a form that has been compared to that of a daisy, and are relatively few, from nine to twelve in number. In the tertian species the merozoites are more numerous, usually from twelve to twenty-four in number, and the corresponding stage has more the form of a mulberry. In *Laverania* (*i.e. P. immaculatum*) the forms of the rosettes, and the numbers of the merozoites in each, are very variable. Most characteristic, however, is the length of time required by each species to complete a generative cycle. In *P. malariæ* a schizogonous generation (*i.e.* a fission generation in the warm-blooded host), from a sporozoite (or merozoite) to merozoite, occupies seventy-two hours; in *P. vivax*, forty-eight; while in *Laverania* it is twenty-four hours or of irregular duration."[29] The paroxysms of fever, suffered by malarial patients, coincide with these fission periods of the various species. In the estivoautumnal form the irregularity of fission in *P. immaculatum* parallels the irregularity of the paroxysms. The gametocytes, or male and female producing cells of this species, are easily distinguished by their crescentic shape. They are usually referred to in literature as "the crescents." In other species the gametocytes are roundish and not at all like these.

The genus of next greatest importance to American pathologists, that is close of kin to Plasmodium, is Piroplasma. In this the carrier, instead of being a mosquito, is a tick. The infected host, in all severe cases, is attacked with hemoglobinuria because of the great ravages of the invading organisms upon the blood-corpuscles. The different species are confined in their depredations to some single genus of vertebrate host or to several genera of a common family. This peculiarity is not uncommon among protozoan parasites many of which have even a closer selective power in that they confine themselves to some particular tissue of the host. The best known species of *Piroplasma* are:

1. *Piroplasma bigeminum*, of American cattle.
2. *Piroplasma bovis*, of British cattle.
3. *Piroplasma parvum*, of African cattle.
4. *Piroplasma ovis*, of sheep.
5. *Piroplasma equi*, of horses.
6. *Piroplasma canis*, of dogs.
7. *Piroplasma muris*, of mice.
8. *Piroplasma hominis*, of man.[30]

The discovery of *Piroplasma bigeminum* opened up a new epoch in protozoan parasitology, the honor of which came to America. The work was done by Prof. Theobald Smith now of Harvard University, in association with F. L. Kilborne. The published report of "Investigations into the Nature, Causation, and Prevention of Southern Cattle Fever" gave us our first knowledge of this kind of organism and of the cause of Texas fever. The name bigeminum was given to the species because of the parasites being linked in pairs at their pointed ends by a thread of protoplasm. The genus gets its name from the resemblance of the organisms to a pear. The species that causes African cattle fever is linked in groups of four, and in the form of a Maltese cross where the viewpoint is favorable. *Piroplasma hominis* is the cause of Rocky Mountain spotted fever of which Dr. L. W. Sambon, the well known authority on tropical diseases, says: "It is impossible to distinguish spotted fever from typhus fever, and I am inclined to think that they are identical."[31] The name "tick fever" has been applied to this disease, in some of our western states, but this is likely to confuse it with the fever of the basin of the Zambesi that seems to have a prior claim to the title. The latter disease is caused by a spirochæta. The next near of kin to Plasmodium and Piroplasma is Halteridium. This genus is nearer to Plasmodium than to Piroplasma. No attempt seems to have been made toward dividing it up into different species as most authors name them all *Halteridium danilewskyi*. These have been found in pigeons, woodlarks, marsh blackbirds, buzzards, ravens, falcons, buntings, horned owls, barn owls, wood owls, finches, jays, song sparrows, Java sparrows, and house sparrows.[32] Prof. J. B. MacCallum, of Johns Hopkins University, while making a study of Halteridium, in 1897, cleared up a puzzling point in the life histories of these organisms as well as of plasmodium. He discovered that what had been taken to be flagella were the microgametes —male forms—of the organism. Neveu-Lemaire has placed Plasmodium, Piroplasma, and Halteridium in the suborder Acystosporea and the next genus we wish to refer to—Hæmogregarina—in the suborder Hæmosporea. Most of the Hæmogregarina are parasites of cold-blooded vertebrates, and all were until lately believed to be so. The species found in cold-blooded vertebrates "frequently quit the corpuscle and become free for a time in the blood-plasma, after which they may penetrate a blood corpuscle again."[33] The following species show their distribution:

1. *Hæmogregarina ranarum*, of frogs.
2. *Hæmogregarina lacertarum*, of lizards.
3. *Hæmogregarina stepanowi*, of tortoises.
4. *Hæmogregarina mirabilis*, of snakes.
5. *Hæmogregarina gerbilli*, of rats.
6. *Hæmogregarina jaculi*, of jerbou.

A number of species have been found in fish and crocodiles. Their carriers, for cold-blooded aquatic vertebrates, are, usually, leeches, for lizards ticks, and for gerbilli a louse.

We can now take a glance at the present classification of the class Sporozoa up to its orders. As it is only necessary to see the position of the genera of Hæmosporidia those of other orders are not included in our diagram.

Class.	Subclass.	Order.	Suborder.	Genus.
Sporozoa.	Neosporidia.	Myxosporidia.		
		Actinosporidia.		
		Microsporidia.		
		Sarcosporidia.		
		Haplosporidia.		
	Telosporidia.	Gregarinidia.		
		Coccidiidia.		
		Hæmosporidia.	Hæmosporea.	Hæmogregarina.
			Acystosporea.	Piroplasma.
				Plasmodium.
				Halteridium.

All known species of the order Hæmosporidia are "parasitic, during the non-sexual schizogonous cycle, in the blood of a vertebrate, and during the sexual, sporogonous cycle, in the gut of an invertebrate host."[34] Prof. Calkins of Columbia University states that "The spores of the malaria organism are not covered by a protective coating as in the majority of Telosporidia, and are, therefore, unsuited for an exposed life outside of their host." Of the Coccidiidia the same author declares that "the permanent cysts contain spores, each of which contains sporozoites which are taken into the digestive tract with the food. Here the cyst membrane bursts or is dissolved, and the sporozoites are liberated. They penetrate the epithelial cells and grow to the

normal size of the adult."[35] Let the reader particularly note the fact that the absence of protective cysts, as is the case with the malarial parasites, is an exceptional one in the whole immense class to which they belong. It is a new, later evolved condition, not found in its kindred organisms. Prof. Minchin informs us that "Only in the comparatively small number of cases in which infection is conveyed from one host to another by an intermediate host, are protective envelopes wanting."[36] In Allbutt's "System of Medicine" we are told that "In the inoculative method of infection characteristic of the Hæmosporidia no resistant spores, but only gymnospores (*i.e.* naked spores) are found at any stage in the life cycle, since the parasite is never outside the sheltering body of the one or the other of its two hosts. In all other Sporozoa (vide diagram) so far as is known the method of infection is a casual or accidental one. Spores cast out from the body of the host are accidentally swallowed by a new host, in which they germinate. Thus the parasitic cycle starts from the digestive tract in all cases. In the casual method the parasite germs must be exposed for a time to the vicissitudes of the outer world, and it is a protection during this period that the characteristic spore-envelopes and cysts are developed, all to be dissolved off or cast aside when taken into the new host. Hence in Sporozoa generally, the exogenous cycle (*i.e.* the cycle outside of the host) is characterized by the formation of protective envelopes which in the endogenous cycle (*i.e.* the cycle within the host) are quite absent, being quite unnecessary."[37] Prof. Sedgwick of Trinity College, Cambridge, England, tells us that "In Gregarinidia and Coccidia the cysts pass out with the feces and enter another host with the food."[38] These facts show us most clearly that the progenitors of the malarial parasites had resisting spores and were able to pass part of their lives outside of all hosts, passing out of their victims without the aid of mosquito or other invertebrate. We have only to remember what has already been said regarding modern classification in order to see, by the aid of our diagram, that "The two orders Hæmosporidia and Coccididia may therefore be regarded as two very closely allied groups of the Telosporidia, which have diverged from a common origin in two directions, in accordance with the difference in their habitat."[39] We can also see that Coccididia and Gregarinidia bear a like relationship. If we will recall the fact that such Hæmogregarina as inhabit cold-blooded vertebrates have a habit of freeing themselves from the blood cells and entering the blood-plasm we can see an intermediate step in the direction of being able to get back into the intestines. This looks very much like a vestige of the old way their predecessors had in getting out of the blood-vessels as the oökinetes pierce the walls of the stomach of the mosquito. As further evidence in this direction we have the case of *Hæmogregarina ranarum*, of the frog, in which almost Coccidian conditions are found. This was the first of these organisms studied and was, until lately, known as Lankesterella. Here is what we are told of it by Prof. Minchin: "With regard to the Sporogony (Hæmosporidian) two types can be recognized, the differences between which depend upon whether the oöcyst is actively parasitic upon the tissues in which it encysts, as in the malaria parasites, or whether it forms round itself a tough protecting membrane within which it is more or less independent of its host or of external conditions, as in *Lankesterella*. The latter case is undoubtedly the more primitive, and does not differ essentially from the state of things seen in the Coccidia. In the oöcyst of *Lankesterella* the number of sporoblasts is relatively small, and each sporoblast appears to give rise to a single sporozoite only. This condition is related, in this instance at least, with absence of an intermediate host. Sporogony and Schizogony here go on in the same animal."[40] It is very evident that we have here the "missing link" that connects Hæmosporidia with the other orders of Telosporidia and gives us the explanation of how the mosquito came to play the part it does in carrying the malarial parasites. The same author further adds that "If the modern conception of the Hæmosporidia as forms closely allied to Coccidia, adapted to parasitism upon blood-cells, be correct, it is reasonable to suppose that the ancestors, at least of the group under consideration, were at first without any special means of dissemination other than the resistant spores and cysts found in Coccidia and Sporozoa generally."[41] But here we meet a difficulty that must not be ignored. Granting that Plasmodium, and other Hæmosporidia of warm-blooded animals, have been derived from organisms that made their homes in cold blood, how are we able to account for the present adaptation to warm blood? Why is it that schizogony is now only possible in warm blood? This is an adaptation that must have required a countless number of generations to be reached. Protoplasm has very great powers of adjustment but they are always slow. In the Acystosporea we have only adaptation to warm blood for schizogony. In the Hæmosporea we have adaptation to cold blood for the same, but, in some of the species, it is carried on in warm blood. Have warm blooded animals been derived from cold-blooded ones and has the transition been gradual? If this is the case then our problem is a simple one. For a mosquito to suck the malarial blood of a man and inject it into a bird or an ox is to kill the malarial organism. The slight differences between the bloods of these destroys the adaptation sufficient to kill. For a mosquito-like insect to have sucked a Coccidian-like parasite from some ancient cold-blooded animal and injected it into a warm-blooded one of the same period could never have established schizogony in the warm-blooded for the first time. The differences in temperature and chemical composition of the two bloods would have been far too great for the dual cycles to have started. Let us, however, suppose that at some time in the earth's history there were no warm-blooded animals but that warm blood came to a few through some gradual process of rise in their temperatures and then our difficulty begins to disappear. If mosquito-like insects then pursued the habit now so common the first transfers would be made from cold-blooded creatures like themselves. The transition from cold blood to cold blood would be slight and, as is reasonable to infer, the chemical composition of the respective bloods would not vary as greatly. Chamberlain and Salisbury, professors of geology and geography in the University of Chicago, and editors of the *Journal of Geology*, tell us that the amphibians were the "ancestors of the whole tribe of terrestrial vertebrates."[42] The transfer from a cold-blooded amphibian to a cold-blooded insect, and *vice versa*, would not be very great. It might, indeed, like the transfer of English rabbits to Australia prove, to the parasite, a decided benefit. It looks as if it had been so for "It is evident that the acquisition of an inter

mediate host is an adaptation which is vastly beneficial from the point of view of the parasite, as is shown by the rapidity by which the diseases caused by them spread in countries where the two necessary conditions occur—the presence, that is to say, both of the parasite and its blood-sucking intermediate host."[43] As early vertebrates, according to the evidence of geology, were all amphibian cold-blooded animals the question would now naturally arise regarding how we came to be warm-blooded. Did the Sporozoan and other parasites force upon the higher vertebrates their warm blood as a protective measure against them? This is a bold question and it is, perhaps, the first time it has been asked. We are all accustomed to take our warm blood as a thing not to be discussed. We treat it as Emerson did the Rhodora by saying:

"I never thought to ask, I never knew,
But in my simple ignorance supposed,
The self-same power that brought me there brought you."

Somehow we have come by it. We cannot conceive of the hosts of insects, amphibians, fish, molluscs, arachnids, crustaceans, annelids, echinoderms, etc., having all been warm-blooded and then becoming cold-blooded. The change must have been in the other direction if the principles of evolution are to be relied upon. In the struggle for existence warm blood survived in all the animals that reached the top in that struggle. How did warm blood come to be a fitness? How did such a change happen to save the lives of the active animals at the top of the vertebrate phylum? As it is common to them all the cause must be equally common among them all. As it differs in height of temperature among them all it must have differed in its intensity of activity for each order or genus of these animals. The normal temperature of a swallow is 118° F., the dog has one of 102° F., and ours is 98.6° F. Why this difference? Why has the ox a temperature of 100° F. while the goat's is 105° F. They all started with the low temperatures common to the amphibians, they have all varied to different degrees, and yet they are all normal to their own kinds. When the rise in temperature began—no matter what originated it—to the animal in which it occurred it was a fever. By the very nature of the case every degree of rise was pathological. It could not be otherwise. Every new change in the ascending temperature was of the nature of disease. The fact that such rises became the fixed temperatures of the creatures—their normal temperatures—proves that it was of selective value. They must somehow have saved these creatures' lives. All kindred animals that failed to respond to the conditions, by a rise of temperature, must have perished. What could it be that thus killed off such animals as did not respond by having fever? Geology tells of no universal refrigeration that such increased bodily temperature might offset. But, even if it did, this would be an inadequate explanation of the phenomenon we are considering. The unevenness of the temperatures among animals and the fact that insects and other lower forms made no such response is evidence that a refrigeration theory would be woefully defective as an explanation. There is one important cause worth considering. It is the single known cause of high temperatures in animals now. No other is known. Pathogenic microorganisms kill. They are responsible for elevation of temperature in animals. We have many certain spotted fevers, owing that their ravages have been coincidental in time with vertebrate phylogenetic evolution. Have they taken any part in giving us our permanent high temperatures? Let us consider the following experimental evidence regarding the effect of high temperatures upon germs and see if it has any bearing on our problem. Bunge says: "According to R. Koch, the most favorable temperature for the tubercle bacillus lies between 37° and 38° C. When kept at 42° C. for three weeks, its further development is impeded. For the gonococcus-Neisser the optimum temperature is between 33° and 37° C. A temperature of 39° C. kills it in twenty-four hours, and one of 42° C. in twelve hours. De. Simone found that the multiplication of the *Streptococcus erysipelatos* stopped entirely at 39° to 40° C., and that the organism died at 39.5° to 41° C. Bard and Aubert found that of the medley of bacteria in the feces, all of them disappeared, with the exception of *Bacillus coli communis*, under the prolonged action of fever temperature. According to Fränkel, the virulence of the septicemic cocci of the sputum is entirely abolished by growing it for two days at 42° C., or for four to five days at 41° C. Pasteur discovered that anthrax bacilli, after being exposed for some time to a temperature of 42° to 43° C., lost their pathogenic character, and that animals when inoculated with the bacilli in this condition became immune to the actual disease. G. and F. Klemper heated broth-cultures of pneumococci for two to three days to 41° to 42° C., and found that when they were injected into rabbits the latter were rendered immune to the infection of pneumococci. These results not only explain the significance of fever, but also indicate how immunity may occur after infectious diseases. * * * The rise of temperature in fever would therefore be one of the processes of self-protection and self-regulation, of which we have so many examples in the body"[44]. Here we discover two important facts, viz., that high temperatures destroy pathogenic microorganisms of many kinds, and that their responses to such temperatures vary for each kind. Some of them have become adapted to higher temperatures than others. This indicates that in their struggle for life they have survived by becoming able to endure higher and still higher temperatures, to which their hosts have subjected them. In the struggle between microbe and host there has not only been a survival of fit hosts, but a counter survival of fitter microbes. First one and then the other has triumphed for a while. The host temperature having reached the utmost limits of normal physiological plasticity in trying to kill the microbes, the latter have become victors. In the fight the cells that succeeded in raising that limit by raising the permanent temperature were the survivors. First the host and then the microbe have survived. With an increase in temperature-endurance on the part of the parasite came an increase in permanent temperature in the host. All parasites and all hosts that failed to make such readjustments perished, while those that did—those with the increased normal temperatures on the one hand and increased resistance to such temperatures on the other—survived to perpetuate their kind. Why there are so many kinds of normal temperature among the higher vertebrates is—per hypothesis—that the parasitism that has had to be overcome has been greater among some than among others. Chief among the agents that have brought man's temperature up to 98.6° F., if this reasoning is sound, have been the malarial parasites. They have been the most persistent enemies of our race and the

Piroplasma

most destructive. In malarial fever "The definite coincidence of the paroxysm with the fission of a generation of organisms has led most observers to assume that the poison, whatever it may be, is set free by the parasites at the time of segmentation"[45]. The young schizonts would be expected, on evolutionary grounds, to tend toward primitive conditions of existence as far as their environment would let them. This is the case with every known organism, and malarial parasites are not likely to be different in this particular from other living things. We should therefore expect that if warm blood affects them unfavorably it would affect the young more than the older and better adapted forms. If there is any lingering affinity toward their sporogonous state or toward their ancient schizogonous state the newly formed young should feel it most. If they have any means of defense against such injury, then at the moment of fission we should expect it to be used. Since this is the very time the malarial patient has his chill, this fact confirms the supposition. Whatever the nature of the poison that is then poured out into the blood the body meets it by a diametrically opposite reaction, that of fever. That more parasites than the malarial ones seek to chill the body in order, apparently, to favor the development of their new broods, has been noticed by Roger, who says: "It must be noted, however, that most of the microbic toxins, when injected in high doses, instead of raising, lower the temperature; they entail death in algid collapse. This result is important, in the first place, because it explains certain clinical facts; then, because it leads to a hypothesis regarding the pathogenesis of fever. It may, in fact, be questioned whether toxo-microbic fever is not due to a reaction of the organism, whether the soluble products of pathogenic agents do not always tend to lower the temperature. If such is the fact, they only excite fever as a reaction of a second order, which expresses a curative effort of the organism. Accordingly, fever is not directly caused by the microbe, but represents, on the contrary, a reaction against hypothermizing substances, and should, when not exceeding certain limits, be considered salutary"[46]. Our deductions, on the basis of Natural Selection, confirm this theory which Roger reached by reasoning from a different standpoint. Our ancestors seem to have unconsciously, or subconsciously, anticipated some such truth as this when they softened the word kill into chill.

191 DEAN STREET.

THE VACCINE TREATMENT OF TYPHOID FEVER.

BY W. H. WATTERS, A.M., M.D.,

PROFESSOR OF PATHOLOGY, BOSTON UNIVERSITY; PATHOLOGIST MASSACHUSETTS HOMEOPATHIC HOSPITAL,

AND

C. A. EATON, M.D.,

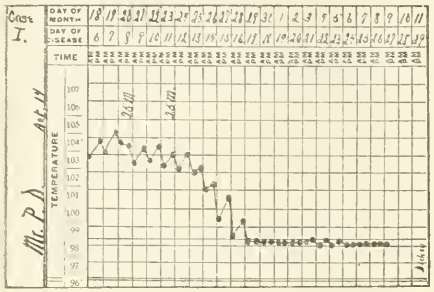
INSTRUCTOR IN PATHOLOGY, BOSTON UNIVERSITY.

AT the present time, in this age of therapeutic nihilism, the advocacy of new methods of treating disease must be cautiously made and must be based upon a foundation uninfluenced by mere personal opinion and individual inclination. Especially is this true of a disease so widely distributed and so serious in its manifestations as is typhoid fever.

The writers of this paper fully realizing these needs, have prepared the accompanying material in the form of a preliminary report of their experiences, hoping, thereby, to induce others to draw their own conclusions from the facts as given. Some months after the regular establishment of work with opsonic therapy in their hospital, in the summer of 1907, a few cases of typhoid fever were placed under the observation and treatment of this department. In certain instances the results obtained were so satisfactory that a further continuance of the study seemed justified.

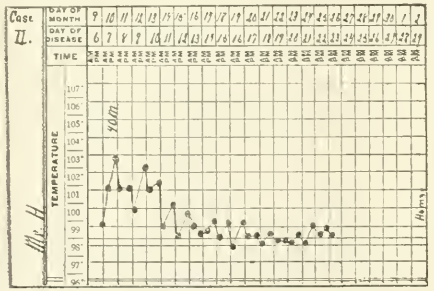
Accordingly, in the summer of 1908, all patients suffering with this disease that came into the services of Drs. E. E. Allen and J. H. Moore, were given routine treatment by bacterial vaccines. No selection of cases was made, the mild and the severe cases, the early and the advanced were all treated. In no instance was there any question concerning diagnosis, roseola and positive Widal reaction being present in each case before treatment was instituted, and usually epistaxis, headache, positive diazo and other less characteristic symptoms were also noted.

We fully realize that the number thus treated is entirely too small to justify any absolute conclusions concerning the ultimate value of the treatment in every case. In the majority of these patients, however, the effects have been so noticeable both to the writers and to the attending physicians that

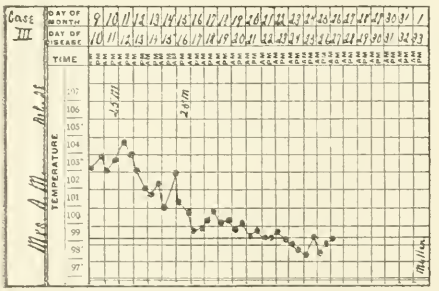


it seems wise to publish them, hoping thereby that others may be encouraged to apply the same method and that we may the sooner obtain a more certain knowledge concerning its benefits and its limitations.

In the majority of the cases, the temperature charts seem to show the effect of the inoculations

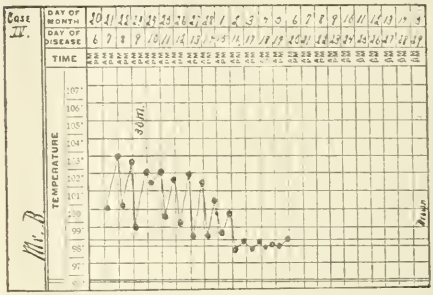


in a very suggestive manner. It has seemed wise, accordingly, to present each of these charts in order that every reader may judge the result for himself. Mere repetition of similar symptoms from case to case would be wearisome as well as valueless. This is therefore omitted. Instead, notes that may be

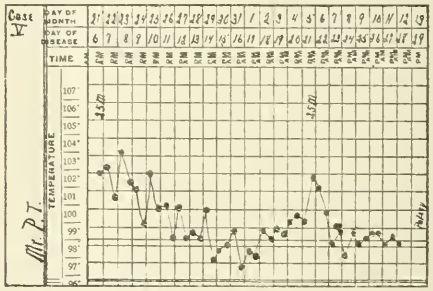


necessary to append in each instance will be made as brief as possible. The statement that clinical improvement was manifest frequently even before the temperature was influenced, and that, even when the temperature was not perceptibly lowered, the physical manifestations seemed to be benefited may be made here as an apparently evident fact.

The cases given are not selected ones, including, as has been stated, the good and the bad, those taken at a favorable time and those already far along in the course of the disease. In all instances the inoc-



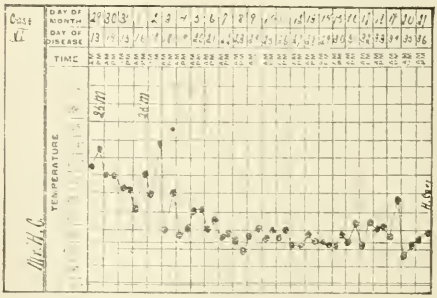
ulations were made into the subcutaneous tissue overlying the biceps muscle, and consisted of a stock emulsion of *Bacillus typhosus* made and standardized in our laboratory and sterilized by moist heat at 60° C. for twenty minutes and by 0.3 per cent. lysol. In no instance could any injurious re-



sult be demonstrated, either by clinical observation or by laboratory investigation, even in those cases in which no favorable response was obtained.

The cases are as follows:

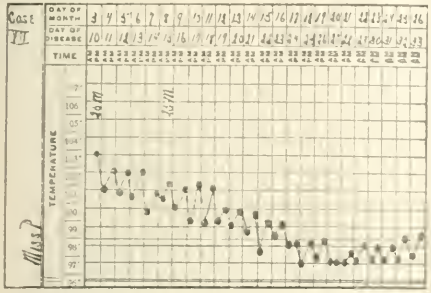
Case I, that of a boy of fourteen years, shows a steadily rising temperature for three days prior to



treatment. The night of the first inoculation, it will be noted, for the first time the temperature was lower than that recorded in the morning. This was followed by a subsequent slight fall which was much hastened by a second inoculation three days later.

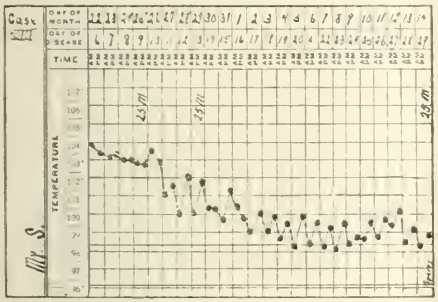
The temperature reached normal on the sixteenth day, where it remained thereafter. The clinical symptoms all showed corresponding abatement.

Case II.—In this case a similar fall is seen which, except for one slight temporary rise, was continuous, reaching normal on the twelfth day.



Case III is of interest because after the fall in temperature subsequent to the first treatment, a beginning rise five days later was apparently changed by reinoculation into a progressive fall continuous with that first noted.

Case IV.—Mr. B. had been sick nine days when



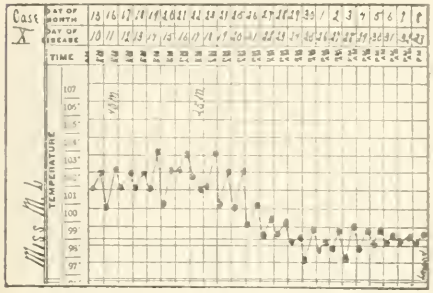
inoculation was given. The various symptoms gradually disappeared thereafter, as the temperature approached normal, which it did seven days after treatment was given.

Case V.—In this case a single treatment was followed by a fall in temperature for eleven days.

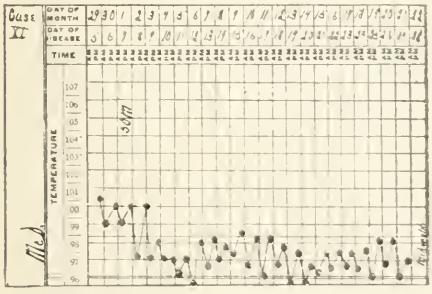
Then began a gradual rise in which purposely no further inoculation was made in order to test the effect of the vaccine. After four days of this rise a second treatment was given, followed by a second decline, this time proving to be lasting.

Case VI shows a favorable response to the first inoculation. Following the second is a period of aggravation of one day, then a prolonged period of amelioration. This last is strongly suggestive of Wright's "negative" and "positive" phase.

Case VII needs no detailed comment. Improvement in all ways was noted from the beginning of the treatment.

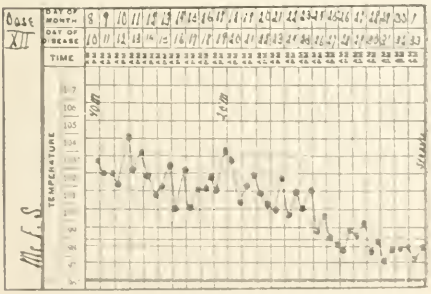


Case VIII was under observation in the hospital four days to determine whether perchance his symptoms might improve without inoculation, which they did not. The result of inoculations is seen,



first a slight "negative phase," then a more pronounced "positive" one. In four days a second treatment on a rising temperature resulted in a continuation of the improvement.

Case IX.—Here inoculation was the precursor of a gradual decline of temperature which persisted



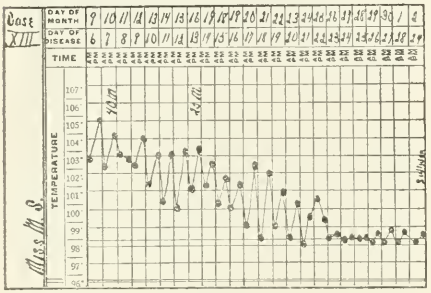
for eleven days. Then, after rising for three days, a second inoculation gave a continuation of the beneficent results.

Case X.—In this case the first treatment seemed to ameliorate the clinical symptoms, although having

no very evident effect upon the temperature. Upon its repetition, however, decided benefit seemed demonstrable.

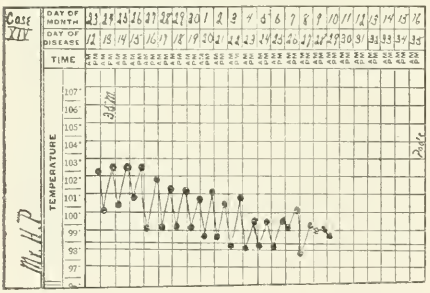
CASE XI was an early mild attack in a strong young man. The temperature curve after treatment is, however, at least suggestive.

CASE XII showed clinical improvement after the



first inoculation. This became more pronounced subsequent to the second, which, given on a rising temperature, was followed by decline by lysis.

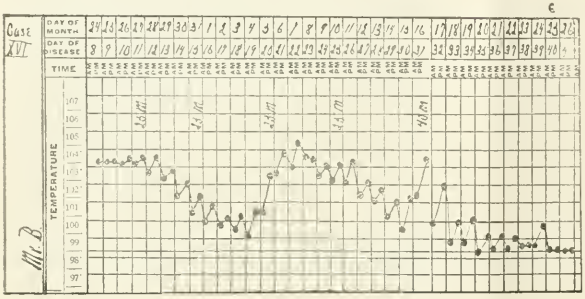
CASE XIII.—Steady decline in severity of clinical symptoms and gradual fall in temperature until it reached normal on the morning of the eighteenth day.



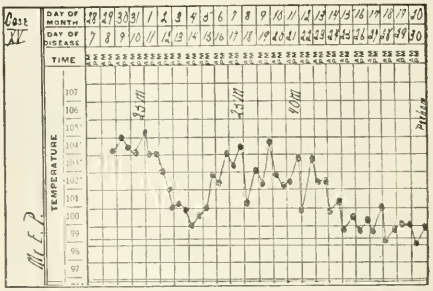
CASE XIV.—A steady, uneventful improvement in all ways following treatment.

CASE XV.—This patient seems to show an unusually significant chart as each of the three inoculations is followed by a distinct fall in the degree of fever. The clinical picture did not, however, show equal variations, it being a steadily improving one from the first.

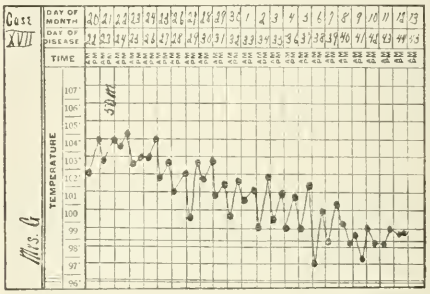
CASE XVI.—In this case the degree of fever which had been practically unvarying for four days, at once began to subside after the first treatment.



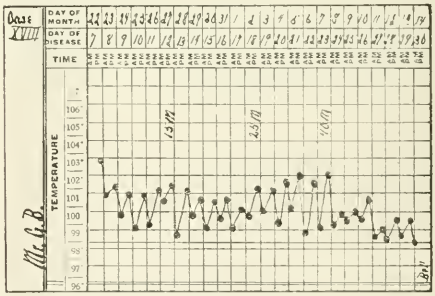
Marked improvement was noted within twenty-four hours, particularly in relation to a very troublesome



headache, which had been persistent and which was entirely gone in two days. The patient, a strong



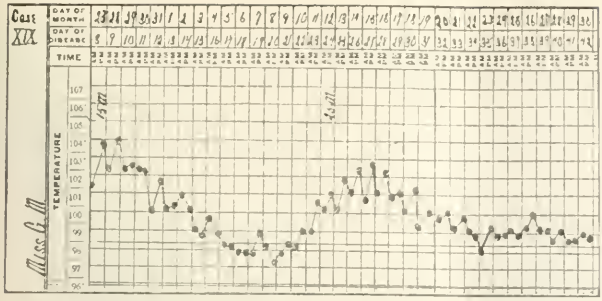
man, showed on the twentieth day a rise of temperature that was apparently little or not at all influ-



enced by repetition of the earlier dose. A second repetition was followed by a fall and another rise. At this time the dose was increased in amount with a much more satisfactory result, as indicated.

CASE XVII.—Here the fall by lysis cannot definitely be claimed as due to the treatment, as the disease was far advanced, having reached that point where decline might naturally occur. The patient was, however, very seriously sick, being on the "dangerous list" of the hospital. Improvement was steady and constant from the time of the inoculation.

CASE XVIII was a mild case of typhoid that seemed to respond to

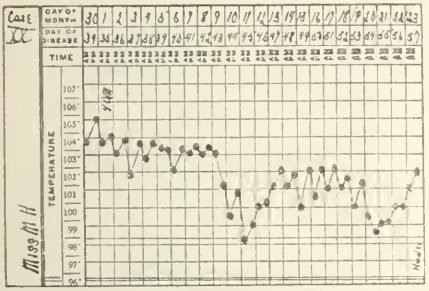


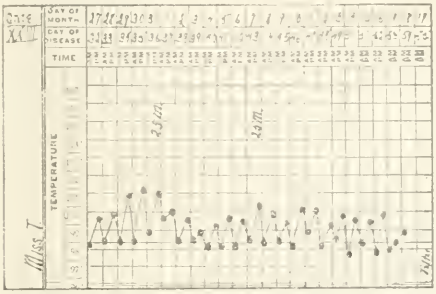
the first, small dose, and to the third, larger one. The clinical symptoms throughout were relatively mild.

Case XIX.—The chart of this case indicates not only the effect following inoculations but a concomitant decline, recrudescence and second decline in the severity of the symptoms.

Case XX was one of the first patients treated. The disease, as had been noted, was in the thirty-fifth day when the first and only inoculation was given. The patient had been supposed to be dying for a day prior to this time. There was a low muttering delirium, with picking at the bedclothes and muscular twitchings. Prostration was great. For two or three days after inoculation slight improvement was noted, which was fleeting. Because of unfamiliarity with the effect of treatment in such severe cases, no new inoculations were made. Death occurred three weeks later.

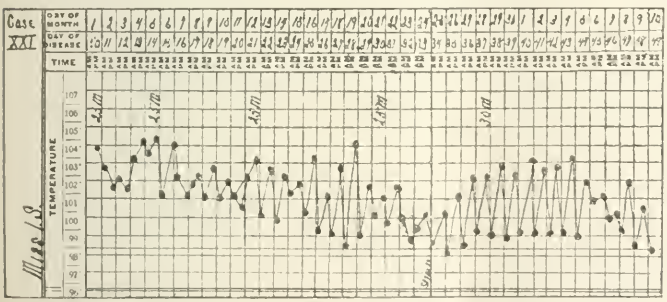
Case XXI.—In this case all seemed favorable in both the clinical symptoms and the temperature chart for more than three weeks.

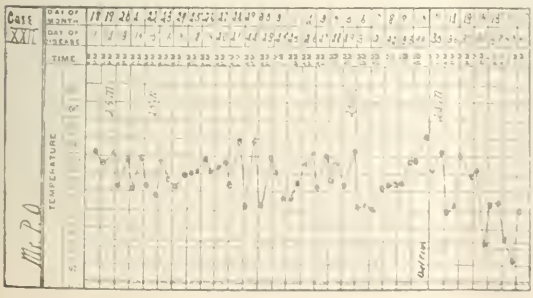




The first and second inoculations in particular seemed to have been followed with good results. Then, in some unknown manner, an abscess appeared on the hand and probably another in some internal organ, producing the septic picture. Pulmonary tuberculosis was another complication. Patient recovered.

Case XXII is the only fatal case among all those patients where treatment was begun during the first four weeks. Mr. O. was mildly delirious on admission, and while the inoculations, particularly the third and fourth, seemed to have some beneficial effect, the clinical symptoms progressed steadily to a fatal termination. Death was the result of a perforating ulcer.





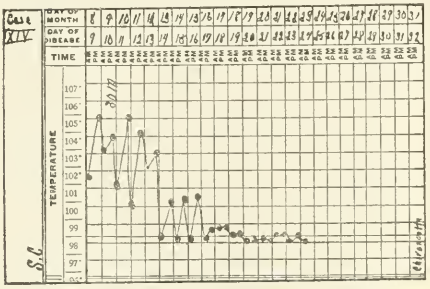
Case XXIII is that of a patient with a relapse of the fever. Each of two inoculations was followed by a fall in the temperature and clinical improvement. Later a latent focus of tuberculosis became active and gave rise to irregularities in the temperature curve. This eventually also fell to normal as convalescence occurred.

Case XXIV shows a very striking fall in temperature subsequent to a single inoculation. The clinical picture, while less spectacular, is nevertheless very decided.

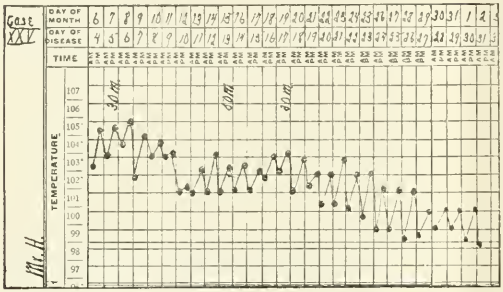
Case XXV.—A young adult who had been for some months much overworked was treated soon after entering the hospital. The entire course of the disease was very mild, there being some slight amelio-

rations of the temperature following inoculations.

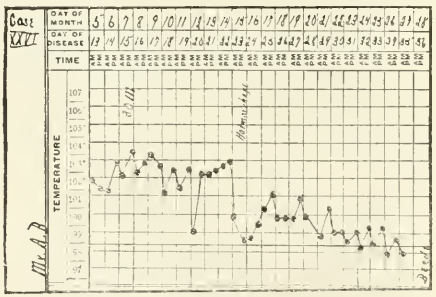
Case XXVI.—This patient had been sick for



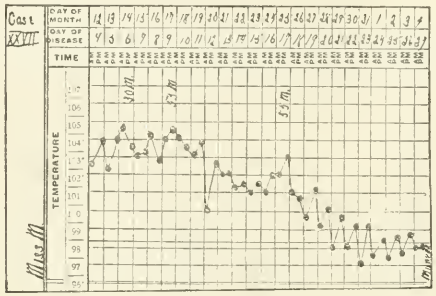
two weeks, part of the time with temperature of 103° to 104°, but had persistently refused to



take to his bed. On admission he was considered to be in an extremely critical condition. Soon

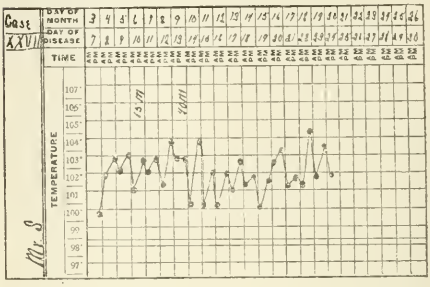


after the inoculation there was noted some improvement which continued to increase, except



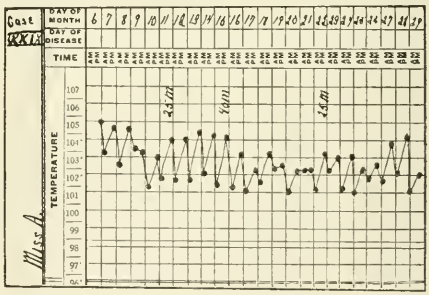
for a few days, when a hemorrhage occurred.

Case XXVII.—This patient, a nurse, was admit-



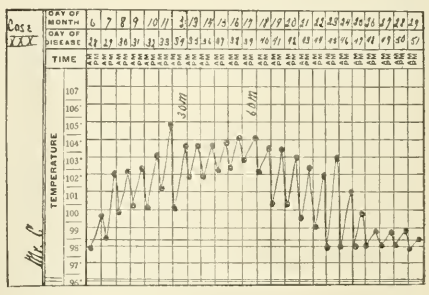
ted to the hospital soon after the disease appeared. Repeated inoculations seemed to be followed by beneficial effects in regard to both the temperature and the clinical symptoms. After about three days subsequent to the first inoculation practically all pain and discomfort disappeared permanently.

Case XVIII.—A man 45 years old. When first seen was in a somnolent condition. Two inoculations being followed by little if any improvement, further treatment was refused by the family. A third inoculation was advised for October 15, but was refused. Two or three days after this the patient, who had been comparatively comfortable, began to get-steadily worse, until death occurred on the 25th. It would seem possible to exclude any aggravation by the inoculations, and it is suggested that from the time when further treatment was vainly advised the disease began to progress steadily



toward a fatal termination.

Case XXIX.—This was a patient practically con-



fined by her habits to an indoor, unhygienic method of living. The disease progressed in a typical manner to a favorable termination influenced but little, if any, by inoculation.

Case XXX.—A boy suffering a relapse. The first inoculation was followed by no apparent result. Subsequent to the second and much larger one, the temperature began to fall steadily, soon reaching normal. An uneventful convalescence occurred.

In concluding this paper, the writers wish to draw no deductions, preferring rather to let each reader form his own opinion. It is of interest to note, however, how similar are a number of these cases to the expectations we would have of them from Wright's work. In not a few instances a period of aggravation, his "negative" phase first appears, followed shortly by the period of amelioration, his "positive" phase. Occasionally we have noticed a first slight amelioration, a short aggravation, and finally a longer amelioration, this also occurring in some opsonic determination as reported by various writers. It has seemed to the writers that the best results have been obtained in those cases in which a brief "negative" phase first occurred. In the thirty cases here reported two deaths are recorded. As one was a patient practically beyond help when treatment was begun, after the disease had been in progress a month, it might seem fair to eliminate it from our reckoning. This leaves one fatality in a patient where treatment was begun at the end of the second week. It is probable that here, as with so many other infectious diseases, the earlier proper treatment is begun the better will be the prognosis. If any modification of method would be advisable in a second series of cases it would probably lie in the direction of using larger doses. As stated in the beginning of this paper, this communication is considered by the writers to be merely a preliminary one. It is advanced with the purpose of inducing a wider application of a method that we are convinced is, under proper conditions, not only harmless, but in a material percentage of cases followed by much benefit.

To the trustees and to the Superintendent of the Massachusetts Homeopathic Hospital, for financial arrangements making this work possible, and to the medical staff, for so cordially cooperating in the work, many thanks are due, and are here gladly given.

THE PRACTICAL VALUE OF TINCTURE OF IODINE AND IODINE CATGUT IN MAJOR SURGERY.*

By WALTER T. DANNREUTHER, M.D.,

NEW YORK.

SURGEON, ST. ELIZABETH'S HOSPITAL; ASSISTANT SURGEON, ST. BARTHOLOMEW'S CLINIC; ASSISTANT GYNECOLOGIST, WEST SIDE GERMAN DISPENSARY.

In a previous paper† I noted the excellent results obtained from the use of iodine as an antiseptic and sterilizer in surgery, advocated its more general application, and suggested further study and experimentation. In conjunction with Dr. Augustin H. Goelet, I have had opportunity to employ this agent and observe the benefits to be derived therefrom in a sufficient number of major operative cases to warrant a rather more elaborate report in this respect. The results of our technique have been so exceptionally satisfactory, that a brief résumé may be of interest.

The patient is carefully prepared for operation in the ordinary manner, particular attention being paid to the alimentary tract. The hands and arms of the operator and his assistants are scrubbed with a liquid soap for five minutes, rinsed off, and immersed in a watery solution of tincture of iodine for one or two minutes. No gloves are worn, except in pus cases. The operative field is thoroughly cleansed with soap and a gauze sponge, a little ether and alcohol dropped on it, and the umbilicus filled with tincture of iodine. If the operation is one of emergency and there is some doubt regarding the efficiency of the preliminary preparation of the skin, full strength tincture of iodine is applied to the whole surface, allowed to remain about thirty seconds, and wiped off. This is always a wise precaution when the patient is colored. Within the peritoneal cavity iodine catgut is used exclusively for ligating blood-vessels, suturing, tying off pedicles, etc., irrespective of the nature of the case. Should pus be present, the sponges used to wipe it out are first dipped in a watery solution of the tincture. The intraperitoneal work having been completed, the peritoneum is closed with a continuous iodine catgut suture, and the wound irrigated with an iodine solution. The aponeurosis is also closed in like manner, and the wound again irrigated. The skin is brought together by a fine subcuticular iodine catgut suture. When dealing with a particularly fat abdominal wall, a small guttapercha drain is inserted in the lower angle of the wound, reaching only to the aponeurosis. A narrow strip of guttapercha tissue is placed over the whole length of the wound, and covered with an ordinary dry gauze dressing, which is left undisturbed for ten days.

Jeffries of the New York Polyclinic proved by a series of laboratory experiments that the abovementioned method of preparing the hands will render them sterile in thirty seconds, and this has been amply verified by our experience in the operating room. The iodine solution used for this purpose consists of a dram of the tincture in a quart of water. The hands may be frequently rinsed in this solution during the course of the operation. The staining of the skin is never deep enough to require any chemical treatment, although if a stronger solution is desired, ammonia water will readily remove any traces of discoloration. Even its prolonged use does not seem to injure the hands in the slightest.

We prepare our own catgut according to Moschcowitz's modification of the method devised by Claudius of Copenhagen. The raw strands of appropriate sizes are immersed in a watery solution of 1 per cent. iodine and 1 per cent. potassium iodide crystals, allowed to remain for eight days, and then transferred to a dry sterile jar covered with gauze. The result is that this catgut is antiseptic as well as aseptic (proved by bacteriological experiments), it absolutely cannot be infected, its tensile strength and pliability are increased, and it is exceedingly cheap. I cannot understand why iodine catgut has not been more extensively utilized, as most suture materials are somewhat expensive and difficult to prepare. The cost of raw catgut strands amounts to very little, anyone can prepare them with the iodine solution, and we then have a suture that can be thoroughly relied upon. We have never had an accident follow its use, al-

*Read before the Tri-Professional Medical Society, New York City, November 17, 1908.

†"The Surgical Value of Iodine," Medical Record, January 25, 1908.

though it has been used in almost every conceivable manner in which a suture or ligature is ever applied. We did have some apprehension of the ultimate result of the first trachelorrhaphy and perineorrhaphy done with iodine catgut, but it served its purpose admirably. We now expect and obtain just as good union by first intention in vaginal cases as in any others.

It was with considerable trepidation that I mopped out the abdominal cavity with gauze sponges squeezed out in an iodine solution. The first occasion for my so doing was a case of appendicitis with a beginning localized suppurative peritonitis. However, more than a year has elapsed and there do not seem to be any excessive adhesions or other untoward effects, and I now do not hesitate when sponging is indicated.

The solution used for irrigating the wound is rather strong: a dram of the tincture to a pint of water. It is poured directly from a pitcher into the wound. This promotes union of the incision, and is the very best method of procuring sterilization of the abdominal wound. Credit is due Dr. Goelet for originating this procedure.

The subcuticular suture of iodine catgut is introduced in much the same way as one of any other material. But the upper end is tied, the skin pushed up on the suture, and the lower end tied, thus converting a five or six inch incision into a one or two inch scar. I have also used this suture in numerous minor surgical operations, and have found it equally as satisfactory.

The guttapercha drain is inserted only in very fat abdominal walls, and simply for the purpose of draining the excessive amount of serum usually extruded in such instances. As a rule, it is removed about the second day. The strip of rubber tissue over the wound prevents the serous exudate from causing the gauze dressing to adhere to the abdominal wall.

The technique I have outlined is suitable for any operation, with slight variations, of course. I used a laparotomy for illustration because it is the most frequently performed operation. The essential features of the whole technique are simplicity, reliability, and economy. Since the adoption of this technique, almost two years ago, we have not had one single instance of stitch abscess or wound infection. In the entire series (unfortunately I cannot give figures) we have had only one death; a case of ruptured appendix with general septic peritonitis. The operation was done as a last resort, the patient being practically moribund, and dying within twelve hours. Nearly all our cases were abdominal operations; the majority gynecological. A long series of nephropexies of Dr. Goelet's is also included. No one's results can be any better than ours have been since the perfection of this technique. I said in my previous contribution, "From my experience with iodine in hospital and clinical work, I have been convinced that it is an agent of high germicidal potency, one of the most valuable antiseptics in our armamentarium, and endowed with remarkable penetrating power. I have used it extensively and for a variety of conditions, and the results have been exceedingly gratifying." This cannot be emphasized too strongly. If this paper but serves to arouse some interest in the subject, its purpose shall have been fulfilled. I am confident that once iodine as an antiseptic is given a trial, the results will justify the continuation of its use.

2030 Broadway.

THE IMMEDIATE VERSUS THE DEFERRED OPERATION FOR EXTRAUTERINE PREGNANCY.*

By ARNOLD STURMDORF, M.D.,

NEW YORK.

When shall we operate for tubal pregnancy? My conviction, based upon a personal experience in forty-three cases and a critical study of the controverted factors, would prompt me to answer, As quickly as the patient and surroundings permit.

My reasons? I have seen and heard of patients who lost their lives by delay, while I have been so fortunate as not to lose a single operative case to the present time.

I have encountered late cases of tubal abortion and hematocele, that might possibly have recovered without operative intervention, had they been fortunate enough to escape the late infections and other secondary pathological changes which brought them to the operating table.

I have never felt convinced that I could differentiate with the certainty essential to the patient's immediate and remote safety between the early stages of tubal abortion which result in an inocuous hematocele, and impending tubal rupture which eventuates in calamity.

While I appreciate and applaud the candor, the frank honesty, and courage that prompt the advocates of this pseudoconservative propaganda to expose a high mortality index in their operative work, I deplore their results and refute their deductions based upon such results. We must not let our sentiment divert our logic; the question at issue involves precious lives, and let me state in all sincerity that were I to realize such a mortality I would not operate early, late, or at all, but would insist upon some one operating, and that promptly.

The time limit set for this discussion precludes all elaborate analyses, so that I shall limit my discussion to a few salient points. It is claimed that not abdominal hemorrhage as such, but operative shock added to the shock incidental to the tubal rupture, is productive of the mortality. Three factors are brought forward in support of this contention: (1) active bleeding from the ruptured vessel is not observed during operation; (2) the amount of blood lost is never lethal according to physiological laws; (3) pregnant bitches with severed arteries never bleed to death.

I know of no operation for shock; and if it is shock and not the loss of blood that dominates the gravity of these cases any surgical intervention, immediate, intermediate, or deferred, must be contraindicated, and it follows as a corollary that, instead of asking, "When shall we operate?" the question naturally resolves itself into, "Why shall we operate?"

The absence of visible spurting from the ruptured artery is due to a very natural series of events, physiological and mechanical. Let us trace this cycle of events. A hemorrhage occurs, severe enough to produce syncope, that means cerebral anemia, which results in a diminution of frequency and force of the cardiac systole and prolongation of its diastole; as a consequence we have a slowed blood current which favors clotting. This is nature's remedy for grave hemorrhage.

We open the abdomen, we find intraabdominal

*Read during a discussion on the subject at a meeting of the Eastern Medical Society, December 11, 1908.

pressure increased in proportion to the amount of the extravasation, our incision converts this hypertension into a hypotension, as a result of which the large abdominal veins dilate at the expense of the arterial contents; we then draw the uterus or tubes into the incision and angulate them, thus obstructing the circulation through the ovarian arteries, and yet we find those who are surprised at the absence of spurting.

The amount of blood lost during the first hemorrhage may be and usually is insufficient to cause death, but how long does nature maintain this condition of slowed current? A short while only—ten or fifteen minutes at the longest. In the mean time the clotting may be sufficient to occlude the rent for a variable period, sometimes for weeks, then nature in her recuperated strength or as the result of some physical exertion on the patient's part, repeats the whole cycle and we at last find the pelvis, even the whole abdominal cavity, filled with clots and fresh blood.

Dogs cannot bleed to death from severance of ovarian arteries. Veterinarians assure us that even the carotid may be severed in a dog without fatal result, owing to the excessive development of the elastic tunic presented by canine blood vessels. Nevertheless, while dogs do not bleed to death from rupture of their arteries—women do—as witness the fatal results following the accidental slipping of ligatures from tied ovarians after operations for other pelvic conditions.

The studies of Crile and others show conclusively that an absolute differentiation between shock and concealed hemorrhage is clinically impossible. Nor can a hemoglobin estimation as recently advocated aid in this differentiation, for we must remember that the immediate result of hemorrhage on the blood is quantitative and not qualitative, consequently the last drops or the first drops must show the same hemoglobin content. We bleed our blood as a whole and not our hemoglobin only.

Every active therapeutic effort must be directed against the etiological factor. This etiological factor is the ectopic pregnancy—remove it.

The contributory and fatal factor is the ruptured vessel—seal it by the only measures known to surgery—prompt ligation.

In short, let us leave dogs and theories aside and operate promptly in ectopic gestation.

51 West Seventy-fourth Street.

A CYST OF THE PROSTATIC VESICLE.

By N. A. MIKHAILOFF, M.D.,

ST. PETERSBURG, RUSSIA.

PROFESSOR OF URINARY DISEASES AT THE IMPERIAL CLINICAL INSTITUTE OF H. I. H. GRAND DUCHESS HELEN PAVLOVNA.

Cysts of the posterior part of the urethra and especially those of the prostatic vesicle have not attracted particularly the attention of surgeons. Most handbooks on urology are silent regarding them and in the literature I have been able to find only two cases reported.

One of them is by Falta (*Prager medizinsche Wochenschrift*, 1898), who found many poppy-sized vesicles with sticky contents in the mucosa of the cavernous part of the urethra, while performing an autopsy on a man, 77 years of age, dead of cancer. This author believes that some of these cysts were distended follicles of the mucosa while others were due to the disintegration of the epithelium of the mucous membrane. The other article is by J. English (*Wiener medizinische Jahrbücher*, 1873, p. 61), who found cyst-like formations near the sinus pocularis in five out of seventy consecutive autopsies which he had performed on newborn children; he thought that these cysts were due to malformations; that is, that they were the result of congenital obliteration of the ducts of the prostatic vesicle.

Nevertheless, cases of this sort do not seem to be very rare. In the first quarter of the present year I had the opportunity to observe seven such cases, the first of which I shall report in this paper. The patient was a student, 28 years of age, single. He consulted us because of severe nervous depression and sexual disturbances. Family and personal history unimportant; no urethritis, no syphilis, no infectious diseases. Sexual desire appeared at the age of ten, and first pollutions occurred at thirteen. The latter were always very painful and the patient tried to prevent them by sleeping with a board tied to his back. After the age of 26 years the pollutions became less frequent and less painful, but were each time followed by very severe headache, which sometimes lasted for forty-eight hours. One year ago the patient had sexual intercourse for the first time, but the ejaculation of semen was accompanied by such a disagreeable sensation that he refrained from repeating the act. The patient is a native of South Russia, tall and well built, and quite normal in his mentality. The left side of his skull and of the face are flattened, causing marked symmetry of the features. Both knee-jerks are exaggerated. The external genitals are normal. Urination is very frequent, the quantity of urine passed every time being small. The right lobe of the prostate gland is atrophied, the left normal. The right seminal vesicle is easily palpable, the left one cannot be felt. Urinary examination is negative.

Cystoscopy failing to help me materially with the diagnosis, I proceeded to an examination with the urethroscope. Local anesthesia with a 2-per-cent. cocaine solution was used, and a Casper's urethroscope, size 28 of Charrière's scale, with a Mercier curve, was easily passed and showed only some passive hyperemia at the posterior part of the urethra. Further on, the instrument met with an obstacle, and I was surprised to see instead of the usual colliculus seminalis a round tumor resembling a cyst, the superior margin of which was clearly defined, while the lower one could not be distinguished. The tumor was about 1.5 by 1 cm. in size. When the instrument was pushed further the tumor seemed to disappear, but reappeared when the instrument was pulled back a little. The walls of the cyst were opaque, reddish-gray in color, and were covered with a prominent network of engorged capillaries.

The patient was operated upon a few days later. After anesthetizing with cocaine, I introduced the same urethroscope and then passed it to an assistant. I then seized the apex of the tumor with a forceps and dissected it out with a knife made specially for the occasion. The contents of the cyst were scanty, yellowish-gray in color, and contained much albumin. The sediment contained a few epithelial cells and some red blood corpuscles, but no spermatozoa. Soon after the operation, the patient's pollutions became quite painless, urination was less frequent and more copious, and the general health was much improved.

A microscopical examination of the cyst-wall showed that it consisted of three layers, the inner and outer being thin and made up of epithelium, while the middle layer was thick, being made up of connective tissue very poor in cellular elements. This layer was about 1.5 mm. thick, the total thickness of the wall being about 2 mm. It became apparent that the structure was a cyst of the prostatic vesicle. As is well known, the uterus masculinus, the remains of the organ of Müller, has no genetic connection with the prostate gland or with the ejaculatory ducts and is quite independent anatomically. A retention cyst can develop within it by the accumulation of secretion of the glands contained in the mucous membrane lining the structure. As it is limited in front and behind by the thick tissue of the prostate gland the cyst must increase in the direction of least resistance, that is, toward the urethra. The increasing pressure of the growing tumor disturbs the neighboring organs and interferes with micturition and ejaculation. In our case such a cyst led to serious disturbance of these functions probably by mechanical interference alone, and in addition it caused a series of general nervous symptoms. The other six cases I shall report in a later communication.

THE EARLY RECOGNITION OF ESOPHAGEAL STRICTURE.

A NEW SIGN OF INCREASED MEDIASTINAL PRESSURE.

By SIDNEY LANGE, M.D.,

CINCINNATI.

RADIOGRAPHER TO THE CINCINNATI HOSPITAL.

STRICTURE of the esophagus as a result of increased mediastinal pressure is not an uncommon occurrence and is rightfully looked upon as an important sign of mediastinal disease. Such a pressure upon the esophagus may be exerted by enlarged mediastinal glands, malignant disease of the mediastinum, aortic aneurysm, mediastinal or spinal abscess, pericardial effusion, chronic adhesive mediastinitis, etc. Clinically such pressure is recognized in two ways: the patient complains of dysphagia and the stomach tube or esophageal bougie meets with resistance at the site of compression.

By the introduction of the bismuth *x*-ray method in the examination of the esophagus it has been shown that the stomach tube or bougie will not register the very earliest encroachment upon the lumen of the esophagus but will show only those constrictions that are of considerable degree. The esophagus is elastic and will stretch to compensate for any *slight* narrowing of its lumen and will allow the stomach tube or bougie to pass. It is only by the use of a very large bougie (and these large instruments are distinctly dangerous) that a slight esophageal obstruction can be detected. And this same inaccuracy attaches to the subjective sign of dysphagia. The patient will complain of difficulty in swallowing ordinary food only after the lumen is considerably narrowed. This fact was brought to my notice in the examination of the esophagi of patients with dilated aortæ and aneurysms.

By a method of procedure outlined in a previous paper* the act of deglutition itself can be studied. Bismuth mush is given to represent the small bolus of soft food, while rice-powder capsules about the size of a quarter are given to represent the larger and more solid bolus. In many patients with slightly dilated and arteriosclerotic aortæ and with small aneurysms, it was found that while the bismuth mush would traverse the esophagus rapidly and normally, the large capsules would pause at the point where the aorta crosses the esophagus. In some cases a swallow of water would serve to carry the bolus past the apparent obstruction; in other cases the capsule would pass only after it had become partially dissolved.

In a majority of these cases, the patients were unconscious of this slight pressure upon the esophagus, not complaining of dysphagia, although after having their attention directed to it, some patients would claim to experience a "sticking" of a large bolus of food such as a partially masticated piece of meat or a bit of dry bread.

It would thus seem to follow that, by the use of the *x*-ray and a large bismuth capsule which would maintain its shape and size more or less throughout its passage through the esophagus, thus testing the capacity of the entire tube and not conforming to any narrow places as does the soft mush bolus, a constriction in the esophagus can be recognized before the dysphagia and resistance to the stomach tube are present.

The application of this method in the diagnosis of mediastinal tumors is shown by the following case:

An adult male, aged 35, had suffered for several months with distress in the mediastinum and with paroxysmal pains which started deep in the chest and radiated up into the neck and arms. His heart seemed normal in size and action. A faint systolic bruit was to be heard over the aortic valve. The lungs were apparently normal and there were no other pressure symptoms evident. The patient was referred to me for an *x*-ray examination. Upon examining the chest with the fluoroscope, I noted a slight broadening of the mediastinal shadow under the upper part of the sternum and, while it was not very marked, in the light of his associated symptoms it was suggestive of a mediastinal enlargement. Upon testing the act of deglutition, the bismuth was seen to pass readily, but the large bismuth capsule lodged under the upper part of the sternum and would not pass until partially dissolved. After this test the patient recalled that he had frequently noticed large pieces of meat would occasionally "stick" in his chest. The diagnosis of mediastinal enlargement with pressure upon the structures passing through the mediastinum was advanced. The case is still under observation.

This bismuth method is of especial value in the *early* recognition of true esophageal strictures, viz., those in which the cause is located in the esophageal wall. The large bismuth capsule will register not only mechanical obstruction but impaired or absent peristalsis as well, and, since with the earliest cancerous infiltration of the esophageal wall there must be an interference with peristalsis, the value of this method is at once evident.

The routine examination of the esophagus by the *x*-ray bismuth method is not an unfruitful procedure. A complaint of dysphagia on the part of the patient should never be lightly passed over as neurotic.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 16, 1909.

VAGARIES OF INFANT FEEDING.

It is probable that more divergence of opinion exists among both scientific workers and practical physicians on the subject of infant feeding than upon any other important question in medicine. Beyond the recognized fact that maternal nursing is vastly superior to all artificial feeding, however scientifically and properly the latter may be carried out, there is no agreement in reference to the reasons why cow's milk should be so much more difficult of digestion, to the proper strength of the food in its various constituents, or even to the amounts required by the child. For many years the opinion prevailed that beyond the different quantitative composition, which, of course, could be remedied by proper modification, the whole trouble with cow's milk consisted in the difficulty with which its proteids were digested by the infant. Biedert in Germany did most to popularize this view which held sway until very recently, when careful analyses showed that casein of cow's milk did not pass into the feces in any such amount as claimed by Biedert, that the so-called curds that were interpreted as masses of undigested proteid consisted for the most part of fat, and that finally the fat and the proteids of cow's milk when fed with the whey of woman's milk were very well borne by children, while the fat and proteids of women's milk mixed with the whey of cow's milk led to frequent disturbances of digestion. That fat is the element that is more frequently productive of trouble has been fairly conclusively shown by the Breslau School of Pediatrics with Czerny and Keller at its head.

Lately the development of biochemistry has led to the application of the newest theories to the question of infant feeding, and Hamburger of Vienna proposed a new and a very interesting explanation of the difficulty experienced by the average child in digesting cow's milk. According to him the young of the human animal, after their intrauterine life, are naturally intended to lead a period of extrauterine dependence upon the mother because the latter alone can provide them with the proteids that are most nearly related to the proteids of which their tissues are made up. The digestive organs of the infant are intended to assimilate only such proteid as is similar to their own and the whole difficulty with the digestion of foreign proteid consists in the extra work which the digestive organs must perform in dealing with these elementary differences. The explanation seemed very ingenious and has been accepted by many and especially by Biedert who, while clinging to his theory of the special indigestibility of cow's proteids, was of course quite willing to use the newest biochemical reasoning to explain this difficulty. Hamburger's explanation has led to a great deal of very careful work in Germany, most of which is admirably reviewed by Uffenheimer in the second volume of the new "Ergebnisse der inneren Medizin und Kinderheilkunde." Uffenheimer's conclusion is that all proteid whether "native" or "foreign" is first broken up into its constituents by the digestive process and therefore no such difference can exist as has been suggested by Hamburger. The fact is rather borne out that so far as our knowledge is concerned the proteid of cow's milk is digested in a manner that is in no way different from the process involved in the digestion of breast milk.

For the time being, therefore, the application of the theory of specific biochemical differences between human milk and cow's milk to explain the problems of infant feeding has not met with any great success. Indeed, the highly theoretical considerations and discussions that have accompanied the controversy have led to a certain degree of feeling against the precipitate application of every new theory to the practical question of medicine. Thus the recent burlesque number of the *Münchener medizinische Wochenschrift* prints an article on the subject of "Side-chains in Infant Feeding." The author tells of having heard "side-chains" so often mentioned in connection with the subject that he decided to try them as an infant food, but met with the difficulty of being unable to find any such substance mentioned in the books on chemistry. He therefore appealed to a friendly druggist, the chemical industry being ever ready at the present day to help the physician in finding new remedies, and the latter in a short time supplied the doctor with a preparation labeled "side-chain powder." This powder the author recommends with much show of learning; indeed, he has tried it clinically on one or two infants and is ready to defend its use against all comers. This amusing account but little exaggerates the true state of affairs, for one need only to follow the pediatric literature for a few months to find every possible substance recommended for the modification of infant food from carrot soup and keffir to "three top ounces from three quart bottles of milk." That no such great difficulty is met with in the practical management of the great majority of artificially fed children as might be supposed from the literature of the subject is probably a fact, provided that pure milk can be obtained. It is the latter problem that has more importance for the well-being of the infants of a community than any other factor of the question.

INEBRIETY IN GREAT BRITAIN.

The consumption of alcohol to excess is undoubtedly a potent factor in the origin and spread of disease, yet it is impossible to lay down any hard and fast rule as to the amount of alcohol which can be taken without danger to the system. Some individuals are able to drink with seeming impunity

an amount of spirit which would be in a high degree poisonous to other persons. Again, there are those who hold that alcohol taken in small quantities is a poison and that the human race would be far better if no spirits whatever were consumed. However, the matter has not been so definitely decided as yet as to allow of the issuing of dogmatic statements. The most perhaps that can be said is that the trend of medical opinion is in the direction of extreme moderation as regards the taking of stimulants, and further that many men advocate strongly total abstinence. On one point, however, there is no divergence of views, namely, that alcohol taken in excess is dangerous to mankind, physically and mentally.

In Great Britain more possibly than in any other civilized country the matter is being dealt with from every conceivable standpoint. The fact is thoroughly appreciated that to the prevalence of drunkenness is greatly due the deterioration of physique and other symptoms of racial degeneration which are manifest among the inhabitants of Great Britain, and especially among the town dwellers. So painfully obvious has become the effects of the drinking habits which characterize a large section of the British people that the aid of legislation has been invoked to endeavor to check this tendency. A bill, known as the Inebriates' Act, was passed by Parliament with the object of checking this evil. The report of the inspector under this act for the year 1907 has been published recently. Dr. R. Welsh Branthwaite, the inspector for England, has this year restricted himself to little more than the publication of figures on the ground that as he is a member of the Departmental Committee which was recently appointed to inquire into the working of the Inebriates' Act he must avoid comment upon those matters of policy which up to the present time have not been debated and considered. In the whole of England there are thirteen reformatories and twenty-two licensed inebriate retreats. The certified reformatories are intended for the reception of 165 males and 1,021 females. Of the 498 persons who were sentenced during the year under the Inebriates' Act and admitted, no less a number of these than 428 were women, a number greatly in excess of that recorded during previous years. The preponderance of women drunkards committed to reformatories in Great Britain was commented upon in these columns two years ago, and it is discouraging to learn that drunkenness among women seems to have increased and to be still increasing in that country.

Dr. Branthwaite draws attention to certain defects in the Lunacy Laws of Great Britain, pointing out that a large number of the persons received at the reformatories are mentally defective and states that "there is no law to detain the most hopelessly defective person after sentence has expired, notwithstanding the recognized condition, certainty of relapse into drunken and disorderly habits, and possible danger to other persons from sudden, passionate violence." The *Lancet* thinks the community would benefit if the reformatory authorities were to be given power, under proper safeguards, to detain such cases until in the opinion of the medical officers there would be a reasonable hope that further relapses would be improbable.

It is difficult to say whether the establishment of reformatories in Great Britain for the detention of drunkards has been attended with good results. The publication of the report of the Departmental Committee referred to above should elucidate matters considerably. At any rate, the statistics issued yearly by the inspector have had the effect of making some points clear, especially that drunkenness is very prevalent in Great Britain, and that it is especially prevalent among women. The future working of the British laws enacted to check the spread of inebriety will be watched with great interest. Up to the present time laws with this end in view have not met with striking success.

Retroflexion of the Uterus.

The majority of gynecologists and gynecological text-books picture the baneful influences and effects of retroflexion of the uterus in such strong colors that the young physician sees the cause of most complaints of his female patients in this malposition of the womb and is instantly ready with the time-honored treatment by means of pessaries or with a recommendation to a gynecological surgeon. Pain in the back, bearing-down sensations, bladder disturbances, etc., are the complaints that immediately suggest abnormal position of the uterus as their cause, and the examination is often considered completed as soon as this condition is diagnosed. It is refreshing, accordingly, to hear another view preached from such a well-known clinic for diseases of women as that of Sellheim in Tübingen. Writing in the *Deutsche medizinische Wochenschrift* for December 3, 1908, Dr. Mayer of that clinic tells of his attempt to find out whether the often pictured effects of retroflexion are really due to it or may simply accompany the condition. The statistics of the clinic alone showed that there was a grave doubt of the primary importance of retroflexion in the production of symptoms, for this malposition of the uterus was found to exist in women not complaining of any symptoms in but slightly smaller proportion than in the patients who came for treatment because of the retroflexion. The study of the nervous symptoms showed that the two had nothing in common, with the exception, of course, of the fact that the neurasthenic patient was quite ready to see the cause of all her infirmities in the "bending of the womb." The fact rather was noted that neurasthenia was at the bottom of most complaints, and the less attention was paid to the local uterine conditions during the general tonic treatment the better were the effects obtained. Especially infrequent were operations for retroflexion, for, as Mayer correctly states, the result of such operations should not be judged by the mechanical change in the position or the fixation of the uterus, but by the effect of it upon symptoms. Such a study of operative results showed that success attended mostly not the special operations for retroflexion involving a laparotomy, but all procedures that affected the prolapse of the organ which often exists in these patients. While spinal pain, lassitude, etc., proved to be neurasthenic symptoms and were little affected, the disturbances of the bladder were materially diminished by anything that remedied the prolapse of the womb. Mayer concludes that retroflexion *per se* needs no treatment, especially in nulli-

paræ; indeed, treatment of the condition in neurasthenic individuals without treatment of the systemic nervous weakness simply helps to make life-long invalids out of many women. That correction of this displacement of the uterus may sometimes be indicated and prove curative is not denied, but as Mayer properly insists individualization is the important moment in all questions of medical art and practice.

Hysterical Fever.

Hysterical patients are such frequent and skillful simulators of various pathological conditions that any unusual phenomenon reported in them is often to be explained by the deception of the observer. This is the usual interpretation of the cases of apparent high fever or rather of hyperthermia that have been reported from time to time in the medical press. Yet the conviction is growing that authenticated cases of this surprising phenomenon have existed, recent observation having shown the great influence exerted by the central and sympathetic nervous systems upon various functions of the organism. There is no inherent impossibility in the conception of hysterical hyperthermia, for the possible ways of affecting the heat regulation of the organism are so numerous that the effect of hysterical conditions cannot be denied. Writing in the *Berliner klinische Wochenschrift* for December 14, 1908, Dr. Morchen reviews such authentic cases of hysterical fever, showing that observers of the standing of Tillmanns, Oppenheim, Dubois, and others, have been compelled to make this diagnosis in individual cases after having excluded all possible causes for the rise of temperature in their patients. Morchen himself had the opportunity of observing three cases of hyperthermia of this character, the surroundings of a sanatorium having given him an opportunity to exclude all possible deception on the part of the patient. All three patients showed a rise of temperature on several occasions during their stay in the sanatorium that led to the suspicion of tuberculosis in one case and of osteomyelitis in another; the third patient was so manifestly suffering from a hyperthermia of nervous character that no other diagnosis could be considered. Osteomyelitis was the diagnosis in the second case because of the appearance of some redness and swelling in the skin of the lower extremities, together with the nervous excitement accompanied by rise of temperature. The local symptoms, however, were shown to have been caused by the presence of several needles introduced by the patient. The characteristics of hysterical fever consist in its irregularity, in its appearance and disappearance in connection with psychic phenomena, and in the very insignificant changes in the general condition of the patient during its course, even the pulse showing but little effect of the hyperthermia. Another interesting diagnostic point is the fact that antipyretics are almost without influence on the course of the febrile reaction; as might be expected, however, baths and psychotherapy exercise a marked control over manifestations of the disease.

Bloodless Operations.

The loss of blood that accompanies extensive operative interference with the tissues of the lower extremities is frequently a most important element in diminishing the chances of recovery from amputations, excision of large portions of bone, etc. It is not to be wondered at, therefore, that surgeons have attempted various methods for obtaining a bloodless operative field in such cases. A well-known method consists in compression of the aorta by means of a tourniquet, but unfortunately it is never to be depended upon, as slipping of the tourniquet is a frequent accident. Momburg has recently proposed trying simple circular compression of the lower portion of the trunk in order to produce a bloodless field in the extremities just as circular compression of the upper portion of an extremity is constantly used in cases of operation on a distal portion. His three cases of compression by means of ordinary thick rubber tubing showed no untoward results whatever. In the *Deutsche medizinische Wochenschrift* for December 3, 1908, Axhausen reports another operation during which Momburg's method was applied, the necessity of saving all the blood possible being of paramount importance to his patient who suffered from tuberculous disease of the hip and was in a very poor general condition. The rubber tube was put on during narcosis and hardly a drop of blood was lost for the forty-five minutes which were taken up by the operation. The "wasp waist" produced in the patient by the constriction was rather disquieting, but no ill effects whatever followed the constriction; thus the operation was made possible in a man who probably could not have stood any interference had it involved considerable loss of blood. The few cases in which Momburg's method has been tried are not enough of course to prove the harmlessness of such construction of the trunk; often enough, however, the decision between operating and not operating in severe injuries about the hip joint depends upon the possible danger from the loss of blood. If the patient dies under conservative treatment the surgeon is usually left in doubt whether an operation might not have been productive of better results, for in the nature of things it is impossible to estimate very well the effect of the loss of blood. In such cases, perhaps, Momburg's method might be tried, so that its value in preventing unnecessary loss of blood may be learned.

News of the Week.

Health Matters.—In his message to the Legislature last week, Governor Hughes, calling attention to the urgent necessity of preventing the spread of tuberculosis, says: "The number of deaths from pulmonary tuberculosis in this State in 1907 was 14,431, of which 8,996 occurred in Greater New York and 5,435 in other parts of the State. Increased provision for hospital care of advanced cases will constitute a most important protection to the community. Greater progress with respect to this has been made in New York City than elsewhere. There are about 1,000 beds there available for tuberculous patients, while in other parts of the State it seems that the number of such beds is only about 250. While it is desirable that more adequate provision should be made in the metropolis, the most striking need is increased hospital accommodation in other parts of the State. I recommend for your consideration the means by which this may be suitably provided, either through State or local authority, or both." Because of the increasing difficulty of securing sites for public institutions, the Governor recommends that Chapter 638 of the Laws of 1903, providing that a hospital, camp, or other establishment

for persons suffering from pulmonary tuberculosis shall not be established in any town unless the Board of Supervisors of the county and the Town Board of the town shall authorize it, be repealed. He also recommends that the question of meat inspection and proper supervision of the slaughtering of animals be considered, and that proper means for protecting the milk supply be sought, so that this may be obtained in the most cleanly and healthful manner, with proper consideration and encouragement for those engaged in the production.

The First Negro Congress on Tuberculosis was held at Tuskegee, Ala., during the third week in December. On the opening day, "Health Sunday," seven meetings were held, and during the six following days the fifteen hundred students of the Tuskegee Institute attended the evening meetings at which addresses illustrated by stereopticon views were given. It was decided at this Congress to establish a permanent tuberculosis committee at Tuskegee with similar committees at other leading negro institutions such as Hampton and Shaw, these schools to work together, each pushing the tuberculosis campaign in their immediate territory. The colored press of the country will be counted upon to spread the propaganda, and the State boards of health will be asked to supply printed matter about the disease and the manner of living which will control its spread.

Association of Tuberculosis Clinics.—A meeting under the auspices of this Association was held at the Waldorf-Astoria on January 8, President John T. Finley of the City College presiding. Mr. Edward T. Devine described the growth of the Association and its work in reaching a class of patients not in touch with the hospitals. He told of the division of the city into districts to prevent overlapping of the work and dwelt upon the particular needs of the Association. Governor Hughes, who has already shown his great interest in the campaign against tuberculosis, warmly commended the Association and made an earnest appeal for money, saying that the men and the plans were ready and the only need was for funds to light the fire.

A Traveling Health Library.—During the last four years the members of women's clubs of Massachusetts have had in circulation a library of books on matters relating to health and hygiene, with the happy result of arousing a great public interest in personal and communal health and especially in the suppression of tuberculosis. It is believed that no other one agent has had a more happy influence upon the public mind, resulting in legislative appropriations for the care of the tuberculous, the establishment of local antituberculosis and visiting-nursing associations, and the foundation of day camps. It is proposed now to extend the library scheme to the country at large, and the General Federation of Women's Clubs (the national body) will recommend that such a library be bought by club women and circulated by them. The chairman of the Health Department of the General Federation is Mrs. Rufus P. Williams of Cambridge, Mass.

After Christian Science.—The annual report of the Massachusetts State Board of Registration in Medicine states that a definition of what constitutes the practice of medicine and a practitioner of medicine is most important, and is included in the medical practice laws of most of the other States, and the passage by the Legislature of an amending section, as follows, is strongly urged: "Persons shall be considered, irrespective of methods of practice, as practising medicine within the meaning of chapter 76 of the revised laws who shall assume or offer to assume the responsibility of determining the nature of disease, deformities or injuries of the human body, having in view the treatment of the same for the purpose of cure or alleviation." An attempt to enact a similar amendment last year called forth strong opposition from the Christian Scientists, and the Committee on Public Health finally recommended "no legislation necessary."

School Inspection in Chicago.—On January 4 the medical inspectors of the Chicago public schools resumed their physical examination of school children. This work was temporarily abandoned, so that the full force of medical inspectors might devote their services to the control of contagious diseases. The work of vaccinating school children will be resumed at once, and completed as speedily as possible.

Illinois Cocaine Law Sustained.—The Illinois Supreme Court recently declared the new cocaine law valid in the first case referred to it since the act was passed by the Legislature. The case in question was a fine of $500, which was imposed on two druggists of Chicago, who were convicted in the lower court of having sold catarrh powder which contained cocaine. It was contended by the accused that this powder was sold by a clerk, but the Supreme Court held the owners responsible.

Rabies in Pennsylvania.—A quarantine of one hundred days has been placed upon a number of cities in the western part of the State of Pennsylvania because of the prevalence of hydrophobia and the presence of dogs said to be suffering from rabies. More than one hundred persons have been bitten and more than five hundred dogs have been killed. At least one death has occurred. The Pasteur Institute of Pittsburg is overcrowded with patients threatened with hydrophobia and there is a long list of applicants waiting for admission.

Typhoid Fever in Montreal.—Upwards of one thousand cases of typhoid fever in Montreal and its suburbs were reported last week.

Cholera in St. Petersburg.—According to a dispatch, dated January 11, seventy new cases of Asiatic cholera were reported in that city during the three days following the Russian Christmas. The increase was attributed to the drunkenness and overeating during the holiday season. Up to the present time the epidemic shows a total of more than 9,000 cases and 3,599 deaths.

The Cartwright Prize.—This prize of five hundred dollars which is offered biennially by the Association of the Alumni of the College of Physicians and Surgeons, New York, will be awarded in June, 1909. Essays in competition for the prize must be forwarded to Dr. H. E. Hale, 752 West End avenue, New York, on or before the first of April. They must contain original investigations by the writer, and must be the work of one person only.

Dr. William T. Bull's Condition has of late improved very slightly, according to the most recent reports. On Sunday evening last, Drs. Blake and Potter issued the following statement: "So many contradictory reports have recently appeared in the newspapers with regard to Dr. Bull's condition and treatment that it has seemed advisable to his relatives and friends that a statement be issued

by his medical attendants. While the rheumatic complications have improved so that he has been able to be about in a wheel chair and go out driving, his general condition has not materially changed and barring complications is not likely to change in the near future."

Dr. Rose's "Medical Greek."—A prominent drug house on the East Side presented to each of one hundred physicians of the city, as a New Year's gift, a copy of Dr. Rose's recently published work on Medical Greek. We understand the first edition of this interesting work has already been exhausted and that a new edition is now in press.

Gifts to Charities.—The will of the late Amos Van Horn of Newark, N. J., contains bequests of $30,000 each to St. Michael's Hospital, St. James' Hospital, Beth Israel Hospital, St. Barnabas' Hospital, the Babies' Hospital, and the Hospital for Women and Children, all of that city.

Dr. James P. Glynn has been appointed Gynecologist to St. Mary's General Hospital of Brooklyn.

Surgeon-General Robert O'Reilly was retired on January 14, after forty-five years of active service in the medical corps of the United States Army, having arrived at the age limit of 64 years. He is succeeded by General George H. Torney, who has had a service of thirty-four years in the medical corps. Dr. Torney's appointment has given great satisfaction both in the army and in the medical profession of the country, his record of efficient service giving assurance that the high standard of administration set by his predecessor will be maintained.

No Ambulance Gongs.—The authorities of two hospitals in New York—the Roosevelt and the Presbyterian—have ordered the gongs removed from the ambulances of their institutions. At the Roosevelt the order affects both electric and horse-drawn vehicles, while at the Presbyterian the electric ambulances retain the gongs. The officials explain that the use of the gongs has tended to cause reckless driving.

The Cincinnati Academy of Medicine, at its regular annual election on January 5, 1909, elected the following officers for the ensuing year: *President*, Dr. R. B. Hall; *First Vice-President*, Dr. S. E. Allen; *Second Vice-President*, Dr. E. S. McKee; *Secretary*, Dr. E. O. Smith; *Treasurer*, Dr. A. G. Drury; *Librarian*, Dr. A. I. Carson; *Censor*, Dr. J. E. Greiwe; *Trustee*, Dr. J. F. Heady.

The McCracken County (Ky.) Medical Society at its annual meeting in December elected the following officers: *President*, Dr. E. B. Willingham; *Vice-President*, Dr. H. H. Duley; *Secretary*, Dr. Vernon Blythe; *Treasurer*, Dr. W. J. Bass. Dr. H. M. Childress and Dr. Frank Boyd were selected as delegates to the State Society meeting at Louisville.

The Jefferson County (Wis.) Medical Society, at its annual meeting in Jefferson, on December 31, elected the following officers: *President*, Dr. Harlow Caswell, Fort Atkinson; Vice-President, Dr. P. F. Stevens, Jefferson; *Secretary and Treasurer*, Dr. C. R. Feld, Watertown; *Censor*, Dr. Claude H. Searle, Palmyra.

The Navarro County (Tex.) Medical Society held its annual meeting on December 23. The following officers were elected: *President*, Dr. T. V. Fryar; *Vice-President*, Dr. Hugh Sloan; *Secretary*, Dr. T. B. Sadler; *Treasurer*, Dr. W. D. Fountain.

The North Central Illinois Medical Association, at its annual meeting, held at Princeton, December 1 and 2, elected the following officers for the ensuing year: *President*, Dr. James F. Percy, Galesburg; *Vice-Presidents*, Drs. Frank A. Turner, Sandwich, and Alfred E. Owens, Princeton; *Secretary-Treasurer*, Dr. George A. Dicus, Streator.

The Effingham County (Ill.) Medical Society elected the following officers in December: *President*, Dr. Chas. F. Burkhardt, Effingham; *Secretary*, Dr. Frank W. Goodell, Effingham; *Treasurer*, Dr. Henry Taphorn, Effingham; *Delegate to the Illinois State Medical Society*, Dr. George J. L. Haumesser, Shumway; *Member of the Medical Defense Committee*, Dr. Joseph B. Walker, Effingham.

The Ohio Association of Medical Teachers.—This association held its first session on December 28, in Columbus, O. Officers were elected as follows: *President*, Dr. J. U. Barnhill of Columbus; *Vice-President*, Dr. W. E. Lewis of Cincinnati; *Secretary*, Dr. E. I. McKesson of Toledo; *Treasurer*, Dr. Charles W. McGaveran of Columbus.

Nurse Dies of Burns.—Miss Eleanor M. Ryan, a nurse from St. Mary's Hospital, Brooklyn, died on January 6 of burns received a few days before. The bed on which lay Miss Ryan's patient and her young baby caught fire from the explosion of an alcohol lamp, but through the nurse's efforts both were saved. Miss Ryan however was severely injured.

Obituary Notes.—Dr. Daniel D. Gilbert of Dorchester, Mass., died at his home of pneumonia on January 2. Dr. Gilbert was born in Brattleboro, Vt., on December 23, 1838. He went to Boston as a boy and was graduated from the famous Boston Latin School and later from the Harvard Medical College in 1861. He then entered the army where he served as surgeon until the close of the war. He was a charter member of the Dorchester Medical Society, and one of the founders of the Dorchester Dispensary. He was a leader in the movement to establish free vaccine stations throughout the State, and was for many years president of the Norfolk District Medical Society and visiting physician to St. Mary's Infant Asylum.

Dr. Joseph Waldo Jewett of New Haven, Conn., died at his home on December 30, of typhoid fever, aged 54 years. Dr. Jewett was graduated from the Medical Department of New York University in 1881, and for a short time was an assistant in the Department of Ophthalmology there. Since 1882 he had practised continuously in New Haven.

Dr. J. H. Ward of Gahanna, O., died on December 25, after a long illness, aged 36 years. Dr. Ward was graduated from the Ohio Medical College in 1901, but two years later was compelled to relinquish his practice because of ill-health.

Dr. Luther Scofield of Maumee, O., died suddenly at his home, on December 20, of heart disease. Dr. Scofield was born in England forty-eight years ago, but came to this country when a young man and was graduated from the Cleveland College of Medicine.

Dr. Frank L. Hughes of Jackson, Tenn., died on December 28, after a long illness, from tuberculosis, aged 26 years. He was graduated from the College of Physicians and Surgeons of Memphis in 1907.

Dr. Henry A. C. Anderson of New York died suddenly of heart disease on January 4, aged 70 years. Dr. Anderson was born in Germany but

came to this country when a boy and was graduated from Bellevue Hospital Medical College in 1870. He was at one time connected with the Department of Health as bacteriologist, and was a member of the Medical Association of Greater New York, the Manhattan Medical Society, and the Society of Medical Jurisprudence.

Dr. Matthew Chalmers of New York died on January 6, aged 70 years. Dr. Chalmers was graduated from the College of Physicians and Surgeons, New York, in the class of 1862, and served in the Civil War as a surgeon. He retired from active practice about five years ago.

Dr. J. C. Bostick of Benton Harbor, Mich., died at his home after a long illness, on December 23, aged 50 years. He was graduated from the Bennett Medical College in 1881.

Dr. Alfred R. Goodrich of Vernon, Conn., died at his home on December 20, aged 90 years. Dr. Goodrich was graduated from the Berkshire Medical College in 1846. He had served several terms as president of the Tolland County Medical Society and as president of the State Medical Society. He was also a member of the Board of Health and one of the trustees of the public library. In the years 1864 and 1868 he was chosen a Presidential elector.

Dr. J. A. Pratt of Brookfield, Mo., died on December 17, after a long illness. Dr. Pratt was born in 1854, and was graduated from the Barnes Medical College of St. Louis in 1894.

Dr. Francis Marion Morgan of Norfolk, Va., died at his home on December 25, after a short illness, aged 62 years. He was a graduate of the College of Physicians and Surgeons of Baltimore.

Dr. Edwin S. Belden of San Francisco, Cal., died on December 29. He was a graduate of the Bellevue Hospital Medical College.

Dr. Charles William Eddy of Marietta, O., died at his home on December 28, of arteriosclerosis, aged 56 years. He was graduated from the Miami Medical College at Cincinnati in 1874.

Dr. Henry Reed Stiles, until 1888 a prominent citizen of Brooklyn, died at his home at Hill View on Lake George, N. Y., on January 8, aged 76 years. Dr. Stiles was graduated from the Medical Department of the University of New York in 1855, and was for some time connected with the Brooklyn Health Department. In 1873 he was appointed medical superintendent of the State Homeopathic Insane Asylum, and four years later went to Dundee, Scotland, to assume charge of the homeopathic dispensary there. Returning to Brooklyn in 1881, he resumed his practice, and in 1882 was appointed Professor of Nervous and Mental Diseases in the Woman's Medical College and Hospital of New York. In 1888 he removed to Lake George where he had since lived. Dr. Stiles was the author of a history of Brooklyn, the first volume of which was published in 1867. He was one of the organizers of the Society for the Promotion of the Welfare of the Insane, the American Anthropological Society, and the New York Genealogical Society, serving as president of the last from 1869 to 1873.

Dr. William Maddren of Brooklyn, N. Y., vice-president of the State Medical Society, died at his home on January 8, aged 63 years. Dr. Maddren was graduated from the Bellevue Hospital Medical College in 1873, and at once began the practice of his profession in Brooklyn. He was a member of the American Medical Association, and the Kings County and Brooklyn Surgical and Pathological Societies, and president of the Brooklyn Gynecological Society. He was attending surgeon to the Kings County Hospital, and consulting surgeon to St. Christopher's Hospital for Babies.

Dr. John J. Quigley of New York died of apoplexy on January 8, aged 43 years. Dr. Quigley was graduated from the medical department of New York University in 1886. In 1894 he was appointed a surgeon in the Fire Department and two years later took up the same service in the Police Department. In 1906 he was appointed Chief Surgeon of the Department, and since then had worked assiduously in bringing the service up-to-date. He was a member of the Academy of Medicine and the County Medical Society, visiting surgeon to the Fordham Hospital, and Professor of Clinical Surgery at Fordham University.

Dr. Edward Roland Snader of Philadelphia was killed on January 3 as the result of an automobile accident. He was 55 years old and was graduated from Hahnemann Medical College in the class of 1878. He was for two years resident physician in Hahnemann Hospital and then become chief of the dispensary staff. In 1886 he became demonstrator, two years later lecturer, and in 1897 professor of physical diagnosis. In 1907 he was transferred to the chair of the practice of medicine. He was at one time clinical chief in the department of diseases of the heart and lungs of the Children's Homeopathic Hospital, and consulting physician to Harper Memorial Hospital.

Dr. Vanroom R. Tindall died at Philadelphia on January 5 at the age of 69 years. He was graduated from Hahnemann Medical College in the class of 1864.

Correspondence.

IOWA'S ENDEAVOR TO CONTROL GONORRHEA AND SYPHILIS.

To the Editor of the Medical Record:

Sir:—For a number of years our esteemed colleague, G. Hardy Clark, M.D., of Waterloo, has with industry and enthusiasm striven to bring about enactments for the control of syphilis and gonorrhea. Dr. Clark's endeavors are endorsed by a number of physicians, schools, clergymen, the Woman's Christian Temperance Union, the Commercial Travelers' Congress of Iowa, numerous church organizations, the Iowa State Bar Association, and other bodies, all acting with the good of mankind at heart. Dr. Clark's present efforts take the form of a letter in which he submits a "bill drafted for the purpose of securing criticism and suggestions that will be useful in shaping legislation for the control of venereal diseases in Iowa." The letter accompanying the draft of the bill gives the "assurance that there is a pronounced demand by the conservative citizens in all parts of Iowa for the firm application of an effective law," and asks the recipient's "sympathetic help in the matter." Dr. Clark's sincerity certainly merits the attention of those whose lives are directed to at least the reduction of venereal diseases. This seems not the place to discuss whether syphilis is purely a venereal disease. Bulkley has led in the elucidation of this matter.

The questions that invite discussion are in the draft itself.

Section 1 provides that syphilis and gonorrhea "shall be reported as other contagious diseases to the County Board of Health for Venereal Diseases hereinafter provided for." It is safe to say that no reputable practitioner will report to any official body or any person syphilis or gonorrhea afflicting any of his patients. The records of such a board would form the basis of so many actions for divorce that additional courts would have to be established to hear them. Families would be disrupted and children left to grow up with but one parent; the other, the divorced one, would be to them worse than dead. The public, knowing the law-abiding

tendency of physicians, would, when infected, fear the possibility of being reported, and consequently would hasten, in even larger numbers than now, to the quacks, who, having no sense of decency, would have no respect for the law.

Section 5.—"From and after the first day of January, 1910, it shall be the duty of every physician and surgeon practising within the State of Iowa to report to some member of the County Board of Health, within 24 hours, every case of syphilis or gonorrhea coming to his knowledge during the infectious stages thereof." This section commands every physician to violate professional confidence, upon which the very basis of his usefulness to society rests. The wording also opens to him the door to perjure himself for the benefit of his patients, by asserting that the case did not come to his knowledge during the infectious stages. The loophole is there. It commands him also to decide when the infectious stage of syphilis and gonorrhea has ceased. The *Journal of the American Medical Association* for December 5, 1908, devotes nearly three pages to the outlines of the steps necessary to determine when a presumedly cured gonorrheic may be permitted to marry. It shows that at least two months are required to determine whether a person in whom the crass manifestations of gonorrhea have ceased, is or is not in the infectious stage thereof. During these two months the patient, if he still be one, may infect a number of others before it can be determined whether he shall be, according to the proposed enactment, reported to the suggested Board of Health. On the other hand, the law might be construed to require the reporting of all cases not proven infectious, which would be manifestly unfair to the patient. With syphilis that presents no symptoms at the time of examination, the question of infectiousness is still more difficult to determine. In many cases it is practically impossible. Ravogli (*Journal of the American Medical Association*, December 12, 1908) emphasizes that while the presence of spirochetes proves the presence of syphilis, their absence does not prove that the patient is free from the disease. The objections presented to this section may become nugatory, when by means of specific sera or other means a diagnosis of ability to infect with syphilis or gonorrhea may be definitely determined. Unfortunately, our methods have not reached that desirable perfection. The means described in the first article cited above as regards gonorrhea entail special experience and laboratory facilities which are not available to all practitioners. Moreover, the people infected actively or otherwise with these diseases are so numerous that the 120,000 physicians of the United States and Canada would not, even if all became venerologists and applied themselves to these examinations alone, have time to care for those of their patients whose ailments are of an uninfectious character.

Section 6 obliges "a person afflicted with syphilis or gonorrhea in the infectious stage * * * to give bond * * * not to exceed $500 conditioned for the faithful observance of and compliance with all rules and regulations * * * controlling the acts and conduct of persons afflicted with either of such diseases * * * ."

Section 7 places the person afflicted with syphilis or gonorrhea in quarantine or isolation until the infectious stage no longer exists. It is estimated by Bulkley and others that New York City alone presents annually an increase of 50,000 people newly infected with gonorrhea or syphilis. It would be pure guesswork to suppose that 10,000 of these are in a position to give bond in $500. These figures are probably far overestimated. Even if correct, 40,000 would have to be quarantined or isolated while in the infectious stages of gonorrhea or syphilis. These infectious periods are exceedingly variable; they may extend from weeks to years. It would be a great economic problem to decide who is to support the quarantined or isolated ones and those dependent upon them during the inevitable inactive period. New Yorkers cannot be deemed prone to acquire pro rata more gonorrhea and syphilis than the inhabitants of other regions; therefore the question presented will apply everywhere proportionately with but slight variations.

Section 10 would make it "unlawful for any person * * * other than duly authorized physicians and surgeons to sell any medicine or compound to cure or purporting to cure either syphilis or gonorrhea * * *." While it is unlikely that practitioners anywhere sell preparations of this class or any other, it may have reference to such physicians in small communities as are obliged to dispense their own prescriptions. In this sense the restriction cannot offer any objection. The same section 10 further forbids advertising for "sale any such medicines or compound." This certainly must have the approval of all who are opposed to such swindles. The same section 10 also obliges every physician to add to each prescription he may write in cases of syphilis or gonorrhea the name of the person to or for whom it is issued. It is not credible that any physician will thus expose to the pharmacist, or any one else, the name of a patient who has either of, or both, the diseases under consideration. Moreover, the patient can easily render such identification futile by giving an assumed name to the physician who would obey his part of the section, if there be such in the profession.

Section 12 would compel every mother or father whose child is so unfortunate as to contract gonorrhea or syphilis to expose the misfortune to the Board of Health, under pain of a fine of from $25 to $100, or to imprisonment in the county jail of from 10 to 30 days. Comment on this section is superfluous.

Section 13 will punish a physician treating syphilis or gonorrhea and not reporting it, by a fine of $100, or imprisonment not over thirty days and revocation of his license to practise. Should this become law, no physician in Iowa will accept any syphilitic or gonorrheic case, and these unfortunates would be forced to travel to another State for the professional care of which they are in dire need, or to go without treatment and thus still more endanger the community.

Section 14, providing as it does a fine of $500 or imprisonment for one year, in punishment for communicating by sexual intercourse either gonorrhea or syphilis, offers to the prostitute a field for blackmail such as has never before been conceived.

The sections not mentioned above deal more with administrative than with medical matters; those presented, however, seem to show that our profession cannot endorse the proposed enactment. The only remotely possible salutary effect of the bill would be in the nature of a warning to the public as to the importance of these diseases. Yet it has ever been demonstrated that mankind cannot be legislated into the paths of virtue, and the perniciousness of unenforceable legislation is so great as to negative any good result that the legislative warning might be expected to effectuate.

No desire for iconoclasm underlies the comments presented. On the contrary, they are offered with the hope that Dr. Clark and others who are prompted by the manifestly humanitarian intentions that underlie the proposed act, will be directed to the only means that now seem feasible for the reduction of venereal diseases—namely, educational.

As long as men are constituted as at present, so long will premarital and extramarital coitus be practised. As long as a certain number of females are prostitutes, so long will they offer themselves to men for hire. Before the sexual millennium arrives, these males and females will disseminate venereal diseases, regardless of any laws that may be placed upon the statute books.

In view thereof, the energy, devotion, and disinterestedness of Dr. Clark and his followers could be more effectually directed to teaching that the only safeguard from the worse than sad results of immorality is to take advice from a regular practitioner as early as possible in the infection.

Terry M. Townsend, M.D.

THE AMERICAN SCHOOL OF TROPICAL MEDICINE AT HONOLULU.

To the Editor of the Medical Record:

Sir:—In a reprint from the *New Orleans Medical and Surgical Journal*, entitled "An American School of Tropical Medicine," my good friend, Dr. Isaac W. Brewer of the United States Public Health and Marine Hospital Service, cleverly takes advantage of Hawaii's freedom from malaria to urge his claim that New Orleans is the best location for an American School of Tropical Medicine, and that Honolulu is too far from abundant malarial clinical material.

In the *Harvard Graduates' Magazine* for June, 1908, Dr. Edward Nelson Tobey, teacher of bacteriology in the Harvard Medical School, has an article on "Tropical Medicine" in which he urges the establishment of an American school similar to those in London and Liver-

pool, England; Hamburg, Germany, and Brussels, Belgium. He suggests that "the Canal Zone would seem to be an ideal place, as it is within easy reach of tropical countries in both oceans, and it will soon be a place where the ships from all ports of the tropics will pass." He says, as to the objects of a school of tropical medicine: "The object of any school of tropical medicine is twofold: First, to spread the knowledge already obtained; secondly, to advance knowledge by research. In a department of this sort one physician should be at work in the medical school to teach the subject, to work up the material brought home, and to aid the investigator in the tropics. * * * In England the schools have a certain annual grant from the government. Expeditions are fitted out by private subscriptions, and the government in many cases has paid transportation charges and allowed the members of the expedition about $2.50 a day for traveling expenses while in the tropics. Our government, if asked, might respond in a similar manner. Why should not Harvard take the lead?"

While departments on tropical medicine in the various colleges and schools outside of the tropics have their place and diffuse a great deal of valuable knowledge regarding diseases peculiar to the tropics, they cannot supply the specific need of a school of tropical medicine situated in the tropics; this fact, I think, is undisputed. I am ready to grant that a certain amount of local pride and patriotic partizanship may color my stated reasons and preferences as to a location, as well as it does the preferences of my dissenting associates, but I think it is easy to make it plain to strictly disinterested parties why Honolulu is at the present time the best location in the United States for an adequate school of tropical medicine. Aside from the continued local prevalence of the peculiar diseases to be studied, and the availability of sufficient clinical material, we must look to the conditions affecting those who are to teach and those who come to learn. As Sir Patrick Manson said in his San Francisco lecture, the typically tropical country was not an ideal location for the study of even typically tropical diseases, because of uncontrollable physical conditions, like hot, humid temperature, and an extreme and almost unavoidable liability to contract infectious diseases.

For this reason Panama, on account of its heat and unhealthfulness, as well as for other reasons, must be excluded. New Orleans, as a populous American city, offers many inducements, no doubt, and my friend Dyer and his efficient associates down there are real allurements. In a teaching staff and material for the study of leprosy, we must acknowledge the superiority of New Orleans over any other mainland city. But New Orleans is not in the tropics, nor has it a climate which can be called comfortable. It has periodical epidemics which are not particularly useful in a scientific way to investigators who reside there, and may be dangerous to their safety. The yellow fever waves which pass that way are not of the nature to contribute much to science, owing to a natural eagerness on the part of residents to limit them as to time and virulence and to the fact that expeditions equipped for special work in epidemics are able to secure all the data needed.

So far as Hawaii is concerned, it has the yellow fever mosquito, and needs not the disease itself as an erratic and ephemeral visitant reaping its deadly harvests at long and irregular intervals. As to malaria, which Dr. Brewer emphasizes, it is indeed a very important disease, and should be familiar to every medical practitioner, but it is not strictly a disease of the tropics any more than is leprosy. Malaria may be studied in the Sacramento Valley, in Kern and other places in California; in Oregon, in Indiana, in Michigan, and even in New Jersey. The very fact that malaria may not be acquired physically as well as intellectually within our borders, is, I am inclined to believe, an advantage to be considered in the establishment of a school of tropical medicine.

Now, such places as Panama, Porto Rico, Manila and other points mentioned as available locations (except New Orleans), do not have, and cannot have, the resident teaching staff quite as necessary to a successful school as the clinical material.

It is as necessary as anything else that the school should have not only the ably imparted theory of a large corps of teachers and demonstrators, but that it should have their actual experience as doctors of medicine in the tropics. Honolulu has this staff, as the Tentative Schedule of the Honolulu School of Tropical Medicine amply shows. Thus, we have two dozen or more physicians, conversant for years with nearly all the various diseases peculiar to the tropics, and in many cases possessing knowledge of diseases like malaria not found here. Honolulu has specialists, too; experts in leprosy, beriberi, plague, and whatnot. What other American city can furnish similar material in leprosy, plague, beriberi, dengue, tropical dysentery and abscess, several fevers yet to be classified, and numerous skin affections? None except the distant city of Manila. And, with this available bedside instruction, what city can furnish the agreeable climatic and social and commercial advantages? As to accessibility, Honolulu is not so far away after all. It has been called the "Crossroads of the Pacific" and the "Pacific Arena," names which will be all the more applicable when the Panama Canal is completed. Five days from San Francisco, every one of them pleasant. Here at hand is the United States Federal Laboratory, a great institution for the study of leprosy, and on Molokai ample equipment for the territorial care and treatment of our large number of lepers.

To "run down" from the mainland is nothing; to "run up to the Coast" is less, after you have started either way, and students of medicine would find the trip a valuable part of their course in tropical medicine, with little opportunity in any case to waste time in the devious bypaths of seasickness.

It is true that Hawaii is a long way from students living in the West Indies and South America; but so is New Orleans a long way from the Philippines, Hawaii and nearly all the Rocky Mountain States. Besides, there are comparatively few practitioners in the West Indies, and fewer (of our own) in South America. Were the school in Honolulu it would have recruits from some of the South Sea Islands, from Australasia, India, the Straits Settlements, and no doubt from Japan and China.

If our government were to decide upon Honolulu as a location for its national school, I have no doubt the institution would be given financial aid by some of our wealthy and philanthropic residents of Hawaii. Already several of them have organized the Pacific Scientific Institution, the objects of which are to encourage scientific work and research throughout the Pacific. It is the intention of the promoters, who have good financial backing, to further the study of the meteorological conditions of the islands of the Pacific; to investigate thoroughly the ethnology, physiography, fauna and flora of this specific field, and to send exploratory expeditions throughout the region. Who can doubt that a school of tropical medicine would not come in for a large share of consideration and aid! Let us not overlook this opportunity to place a school where it properly belongs. Greater demands have been successfully made by poorer beggars.

E. S. Goodhue, M.D.

The Doctorage, Hawaii.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LEAGUE OF MERCY — RHEUMATIC AFFECTIONS — POISONING OF EMIGRANTS BY FERROSILICON — IMPORTED MEAT, NEW RULES.

London, December 24, 1908.

This week it is the turn of the League of Mercy to hold its annual meeting—the ninth of the series. You are aware that the League was established under the auspices of the Prince and Princess of Wales to help the King's Fund by organizing a collection of small sums—though it does not decline large ones. A message from the Prince was read expressing the gratification of the Princess and himself at the steady progress and expansion of the work. As he anticipated, its extension to the home counties has led to grants, to hospitals outside the area of distribution of the King's Fund. The chairman reported that an extra £1,000 had been loaned to the King's Fund this year. The honorable treasurer said the total collected, including promises, was £22,100, or more—the largest of any one year. They had given £1,516 to the Home counties hospitals and £19,000 to the King's Fund. The value of small subscriptions is illustrated in the fact that out of a total of £43 in an East End district 4,707 individual pennies were subscribed in the tenements. During its nine years' life the League has given £116,000 to the King's Fund. Clearly this organization is a powerful support to hospitals. There are now 322 recipients of the "Order" of the League—a distinction conferred only for personal service. A number of new presidents were appointed, and so the branches grow.

Counterirritation, especially by means of blisters, has so long been an accepted treatment in rheumatic affections that we can safely anticipate that in some form or other it will from time to time come up for reconsideration. Forty years ago or more small blisters an inch or two from each swollen joint were well tried in acute rheumatism. A little later, larger blistering was recommended by leading physicians in chronic cases. Still later, I saw the plan applied in so-called rheumatoid arthritis. In recent months we have heard of good results by applying blisters along the spine, chiefly in the neighborhood of the cervical and lumbar enlargements. On the 9th inst. the plan was brought before the Bacteriological Society by Mr. W. J. Middleton of Bournemouth, who showed a patient who had recovered health and freedom of locomotion under this treatment carried out by Dr. S. G. Champion. Notes of other cases were added—27 in all—besides some of paralysis and hysteria. The counterirritation is kept up for a considerable time, and it is suggested that the nervous system is improved and that toxins may be removed in the discharges when the blisters are kept open. Dr. Luff's comment on the paper was that blisters to the spinal region for various joint affections had not compared favorably with other treatment. Dr. Armstrong of Buxton said he had for the last twelve years paid special attention to the so-called "joint centers" in the cord, as he thought in all cases of arthritis the nerve nutrition of the joints must be affected. Mustard, acetic acid, and other counterirritants were used in his earlier work. Later he had tried the blistering method in 16 cases of severe rheumatoid arthritis and obtained improvement to some extent in all. He had also for about four years been using the electric cautery. He applied it to the sides of the cervical enlargements when the upper limbs were affected, and to the lumbar enlargements for the lower. He did not call it a specific treatment, nor could it exclude the necessity of eliminating all sources of reflex-irritation—gastric, septic, or other. In a number of cases the results were gratifying. Dr. Buckley said he had given a fair trial to counterirritation of the skin over the spine, and thought all plans including Paquelin's cautery, which he preferred, alleviated pain, but had no curative effect. He did not think they could cure, for he believed the disease was of bacterial origin. Dr. Llewelyn Jones spoke in favor and Dr. Mantle against the method. In reply Mr. Middleton said many of his patients and of Dr. Champion's had tried all kinds of treatment both at home and abroad. The foregoing discussion may be compared with that on acute rheumatism at the Therapeutical Section of the Royal on the 1st inst. It was opened by Dr. R. Stockman, who exhibited many charts to show the prompt fall of temperature under the use of sodium salicylate. When the initial fall was delayed a larger dosage would be effective. Allied drugs, as salicin, were also shown to have similar effects. In one group of cases the synovial membranes were principally or solely involved. In another group the surrounding fibrous structures were much affected, and these cases were more chronic and more resistant, requiring large doses. Dr. Lees said the present treatment failed to arrest the disease because the arthritis alone was attacked and a beneficial effect on the heart was scarcely hoped for. He recommended salicylate in large doses combined with twice the amount of bicarbonate of sodium. For an adult 150 grains of salicylate daily, increasing by 20 to 50 grains until the temperature fell to normal. Unpleasant symptoms might be met by decreasing the dose, but again coming back when they disappeared. Sodium salicylate was not, as so often supposed, a depressant to the heart. Two precautions should be observed in this treatment: namely, give enough of the bicarbonate to alkalinize the urine and prevent constipation. Dilatation of the left ventricle disappeared under this medication. An icebag was useful in pericarditis and myocarditis, but before applying it any indication of dilatation of the right ventricle must be relieved by leeches. I have summarized these two discussions in consequence, perhaps, of a long talk I had this morning with a friend on the unsatisfactory results of treatment in numerous cases. He told me of two apparently parallel cases sent to Buxton with opposite results; of two sent to Droitwich, one of which seemed nearly cured and the other "as nearly killed." These convinced him that we could never be sure that anyone would benefit by a course of treatment, the experience of drugs being similar. The same experience applied to massage, passive movements and electric measures. I was obliged to admit facts and could not suggest what conditions varied so far as to determine the contradictory results. As a final note I may mention a case sent to Buxton by Dr. F. Booth after he had obtained a remarkable degree of improvement by persistent lavage of the intestines. Three quarts of warm water in which two tablespoonfuls of magnesium sulphate were dissolved were passed into the colon daily by a long tube attached to a Higginson's syringe. Thus the lower bowels were well irrigated, while to disinfect the smaller, castor oil and betanaphthol were given simultaneously. Offensive stools and alternating constipation had been marked in this case and the determined attempt to deal with it had been soon successful in these respects, and then pyrexia and the joint symptoms had begun to abate. The lavage was, after some weeks' daily use, dropped to three times a week, and eventually to once a week. The last note from Buxton says that all the joints except one knee have recovered. It will be interesting to hear whether that also recovers, though few patients may be able to continue so prolonged treatment, and perhaps not many are so evidently connected with intestinal trouble.

The deaths of five Jewish emigrants on a steamer have been explained, as due to fumes given off from ferrosilicon which formed part of the cargo. The analyst said he had examined a sample from the cargo, and that it was very dangerous. It was used by steel manufacturers, and regularly imported from Belgium, and was more affected by sea air than land air. The medical officers found no evidence of ptomaine poisoning or of cholera, but signs of poison by noxious gases. The captain of the vessel said he did not know it was dangerous, and had "never heard of the stuff before." The importers accepted all responsibility. The firm had carried ferrosilicon for years with no mishap, but had lately given instructions to refuse it. The present consignment was the first breach of the rule, and it was accepted by clerks at Antwerp on the assurance of the German manufacturers that a new process had eliminated all danger. The verdict was that the deaths were due to gases emitted by the ferrosilicon, and the captain was not to blame.

New regulations have been issued, to come into force with the new year, as to the importation of tinned meat and "boxed meat." Medical officers of health are to satisfy themselves that the pieces of meat can be individually separated and examined; (2) that any piece can be identified with the parts of the carcass the box is stated to contain. Pork is not to be admitted in portions less than a whole carcass and must be accompanied by a certificate that the pig was not diseased. Other regulations will remain in force.

Progress of Medical Science.

Boston Medical and Surgical Journal, Dec. 31, 1908.

Early Cervical Lymph Node Enlargement, the Sole Sign of Carcinoma of the Esophagus.—O. W. H. Mitchell reports one case in full, discussing from its data the question of differential diagnosis from tubercle, syphilis, and Hodgkin's disease. He says that any enlargement of the cervical nodes in the adult should always awaken suspicion of malignancy. Metastases may prove more malignant than the primary deposit. The latter may give no signs or symptoms till late in the disease and in fact may be discovered only at autopsy. In the present case a preliminary excision of a node revealed the malignant nature of the disease.

Morris's Point of Tenderness as an Aid in Diagnosis.—J. C. Hubbard declares that the point has by no means the importance attached to it by Morris. The abdominal lymphatic glands, becoming secondarily inflamed, cause tender areas. The area found tender on examination is somewhat of a guide to the organ primarily infected and therefore in certain cases may be an aid in diagnosis. In acute appendicitis tenderness at Morris's point is of less importance than the symptoms caused by the appendix itself. In chronic appendicitis tenderness at the point may be of distinct diagnostic value. Tenderness at this point, even though the only physical sign, makes the diagnosis by the rule of chance probable. When combined with tenderness at McBurney's point the diagnosis becomes more certain. Its absence does not rule out appendicitis and it may occur in other conditions.

New York Medical Journal, January 2, 1909.

A New Instrument for the Estimation of Urinary Acidity.—H. R. Hanower's device is a graduated test tube to replace for the clinician the familiar buret. It is easy to handle, is just as accurate as the buret, much less expensive, and simple in use. The new acidimeter is so graduated that 10 c.c. is the first measuring

point. From this upward the tube is so graduated in fifths of a degree to 100 degrees, each degree representing the amount of decinormal sodium hydroxide solution required to neutralize 100 c.c. of urine. The tube is filled to the 10 c.c. mark and two drops of phenolphthalein indicator solution are added. Then with an ordinary dropper decinormal sodium hydroxide solution is added, the tube being inverted after each addition till the color changes from a yellow to a light rose pink. The acidity is now read off in the tube at the level of the tube. The normal acidity of a mixed twenty-four hours specimen should lie between 30 and 40 degrees. If the urine is alkaline and the degree of alkalinity is desired, we substitute for the sodium solution decinormal hydrochloric or oxalic acid, the pink color present being first discharged by the acid.

Bluish Discoloration of the Conjunctiva from an Indelible Pencil.—A. Bray reports the case of a young woman who was sharpening an indelible pencil and accidentally received a bit of the lead in the eye. Examination showed a small conjunctival laceration on the lower lid and both the lid conjunctiva and the bulbar conjunctiva up to the lower corneoscleral margin was a dark purple blue mass. An alkaline wash was ordered and the next day the eye was clear. In fact, the stain disappeared in eight hours. These indelible pencils contain the aniline dyes and do not form an insoluble salt with the albuminates of the tissues.

Toxic Effects from Bismuth Subnitrate.—E. G. Beck has been able to find eight authentic cases of bismuth subnitrate poisoning and gives a bibliography of the literature covering, as well as the reports of certain experiments on animals. His conclusions follow: (1) Bismuth subnitrate administered by the stomach in small doses is harmless. (2) In the presence of certain bacteria or feces of children bismuth subnitrate will liberate nitrites, which will be absorbed by the intestines and eliminated by the kidneys, and if the production is faster than the elimination, methemoglobinemia will result. (3) In large doses by mouth it is liable to produce an acute nitrite poisoning, characterized by cyanosis, collapse, methemoglobinemia, and may terminate fatally. (4) Rectal injection of small doses of bismuth subnitrate may cause nitrite poisoning much quicker and more severe than when administered by mouth. (5) Children are more susceptible to nitrite poisoning due to administration of bismuth subnitrate. (6) Persons suffering with intestinal putrefaction are very susceptible to nitrite poisoning when bismuth subnitrate is injected into the bowels. (7) The bismuth injected into these sinuses, and encapsulated, will be gradually absorbed, and may be found in the liver, spleen, muscles, and intestines. (8) Characteristic symptoms of black borders of gums, ulcerations of mucous membranes, diarrhea, desquamative nephritis may appear several weeks following the injection of the paste. (9) After the injection of large quantities of the bismuth paste into suppurating sinuses, mild symptoms of nitrite intoxication may appear. (10) The acute nitrite poisoning is to be regarded as a distinctly separate affection from the more chronic bismuth absorption. (11) Radiographers should employ some other preparation of bismuth than the nitrate, and refrain from injections of subnitrate into the bowels, especially if intestinal putrefaction is present.

The Responsibility of the Family Physician Toward Tuberculosis.—S. A. Knopf says that any physician who is able to make in a given case a definite diagnosis of tuberculosis should inform the patient and his family. The course of treatment as to climate, diet, etc., must depend on circumstances, but the usual prophylactic measures should be begun at once, whether the patient remains at home or not. If the law requires registration, this should be done. Very sick cases should not be sent away from home. Care should be taken in regard to the children of a tuberculous parent who remains with them. The choice of a future career often determines whether young people will or will not have the disease. Thus the son of a consumptive printer should choose some other occupation. The daughter of a tuberculous mother should never be a seamstress. Tuberculous patients should not marry. At the present time they will, in spite of all advice, and if the laws of one State prevent it they will simply move to an adjoining State. If a tuberculous woman becomes pregnant, emptying of the uterus may be justified to preserve the mother's life. But prevention of pregnancy is better and the author deems it justifiable to advise it. There is no need of turning the treatment over entirely to the specialist. The family physician should be able to meet every requirement. Knopf deems it a great error to hand patients over entirely to faith healers of all kinds, Emanuel movement men, etc., though the hopeful methods and measures of such persons are highly commendable.

Journal of the American Medical Association, January 2, 1909.

School Hygiene.—L. H. Gulick insists that the problem of the health of school children demands special technical skill for their solution, and that school boards should take as much pains to secure such aid as they do in matters of architecture and business details. As instances, he refers to vision and its defects and says that, notwithstanding its importance, there is hardly a school board in America that has in its employ a technical expert to decide on questions of eyesight. This is not alone in its neglect; he mentions also the unnatural sedentary conditions of school life, the effects of respiratory obstruction by adenoids, enlarged tonsils, etc., on the capacity of the child, the increase of nervous symptoms, the effects of fatigue, of home study, etc., all of which are subjects that properly fall within the class that should be considered by educational authorities. Until they are thus considered with all the aid that science can give, no contribution of permanent value to physical development will be made, he says, in the field of education. There should be organized under every board of education a department of school hygiene with adequate authority, responsibility, and financial support.

Backache in Women.—L. F. Garrigues says that backaches in women are so common and so far-reaching in their effects that their thorough understanding is of great importance to the physician, yet we find practically nothing on the subject in text-books. Leaving out of consideration those due to rheumatism or strain, he confines himself to the subject of the pelvic backaches, and more especially those caused by disease of the internal pelvic organs and cellulitis of the uterosacral ligaments. Pelvic backache is of two kinds. In one there is pain and tenderness at the level of the fourth and fifth lumbar vertebræ, where the spinal nerve center governing the internal pelvic organs is situated. The treatment of this form, to be effective, necessitates the cure of the underlying disease. In the second variety there is a tender spot on either side of the second sacral vertebra which he contends is due to cellulitis of the uterosacral ligaments. If only the site of the pain is considered, incipient sacroiliac disease or caries of the fourth or fifth lumbar vertebra might be mistaken for pelvic backache, but the first of these is rarely bilateral, and is accompanied by pain on compression of the iliac bone, while the other has some spinal rigidity and is especially aggravated by jars. Neuralgia is less sharply localized and usually causes a more intense, intermittent pain, instead of a dull and constant ache. In rectal inflammation and fracture of the coccyx the pain is referred to the coccyx. In pendulous abdomen there is a dull, constant dragging pain, referred to the lumbar region, probably due to the traction of the mesentery, but it is relieved by lying down or the wearing of a supporter. The only variety of backache peculiar to women, Garrigues says, is that due to cellulitis of the uterosacral ligaments, characterized as stated above, by pain at the outer sides of the second vertebra, and he goes at some length into the description of the anatomy and pathology of the condition. The symptoms in an uncomplicated case are backache, referred to the spots described, which becomes worse on exertion, and there is a distressing sense of weakness. Pain on sexual intercourse is often marked. The diagnosis by vaginal examination is easy if the normal conditions are known and the symptoms of pain on manipulation of the ligaments is brought out and their abnormal conditions recognized. The treatment is to put the patient to bed, apply an icebag to the lower abdomen, and to administer active saline cathartics; tampons dipped in a 5 per cent. solution of iodine-glycerin are useful and hot douches may be employed, though he thinks that their value is overrated. Besides this, the cause, if still present, must be removed. If suppuration occurs, or before in a severe case, vaginal incision and drainage should be employed, care being taken not to enter the peritoneal cavity. In mild chronic cases, painting of the posterior vaginal fornix with tincture

of iodine, two or three times a week, also 5 per cent. ichthyol-glycerin tampons or vaginal suppositories inserted at night, are useful. If these measures do not produce sufficient absorption, pelvic massage gives fairly good results, but seldom complete cure and is somewhat tedious and painful. To overcome these objections, it occurred to Garrigues that section of the uterosacral ligaments would be rational and not a dangerous treatment, and he reports two cases successfully treated in this way. In answer to possible objections that these ligaments are an important uterine support and that severing them might lead to a prolapse, he answers that the peritoneum holds the divided ends of the ligaments from dropping too far apart, and the gap must eventually be filled by a nerveless fibrous tissue.

Typhoid Agglutinins in Meningitis.—W. Becker and G. C. Ruhland report a case of cerebrospinal meningitis, in which the typhoid agglutination test was positive within twenty minutes, a dilution of the serum of 1 to 100 was used on a typhoid culture in bouillon not over twenty-four hours old. The autopsy revealed the lesions of meningitis and the presence of the specific diplococcus, but no evidence of typhoid. While they are almost certain that the specific agglutinins of typhoid and for the Diplococcus intracellularis are distinct, and that higher dilutions of the serum of the patient would have ultimately agglutinated only with the meningococcus, yet the case appeared to them of sufficient interest to make its publication desirable.

A Deceptive Case of Leprosy.—C. J. White and O. Richardson give a full and interesting account of a case of leprosy which baffled the diagnosis of a number of competent dermatologists, including some of the best known in this country and Europe, such as Bertarelli, Crocker, Hallopeau, and others, who unanimously considered the case one of syphilis. It was only when the nose began to develop its convincing symptoms with the finding of the bacilli that the authors were able to reject the diagnosis of specific disease.

Climate and Tuberculosis.—C. L. Wheaton upholds the value of climate in the treatment of tuberculosis. Elevation above the sea, dryness of air, sunshine, winds, variability of air temperature, electricity of the atmosphere, are all, he says, contributing factors in the arrest of tuberculosis. The higher strata of the atmosphere are the freest from impurities, atmospheric cleanness and transparency is a test of purity, and the bactericidal action of sunlight is recognized by all. Though the results of sanatorium treatment in so-called unfavorable climates have exceeded expectations, it is no reason why we should deny that some climates are better than others and possess attributes beneficial to the treatment of pulmonary disease. While recognizing the fact that most victims must avail themselves of home conditions and that change of climate has often been injurious and too indiscriminately prescribed, let us still acknowledge that, in selected cases, the advantages of climate are not all fictions and that it plays its part in the hygiene of tuberculosis.

The Lancet, December 26, 1908.

Arthritis Deformans.—A. H. Tubby gives a general description of this disease, contrasting it with Still's disease. Rheumatoid arthritis or arthritis deformans is, in the authors' opinion, probably an autointoxication. He notes that almost invariably the patients have carious teeth. Under the general name of the malady are grouped various types, such as the hypertrophic or osteoarthritic and the atrophic or rheumatoid arthritis proper. In the former the general health of the patient is to be maintained and he should live on a dry soil. A warm climate is advisable for the winter. Excess of nitrogenous extractives or carbohydrates in the diet is to be avoided. Locally the joint should be used moderately and electricity with massage is of service. In the atrophic form, if the patient is young the general treatment is very much as in incipient tuberculosis. The various forms of fermented milk provide an excellent diet, especially the Metchnikoff milk, and the lactic acid bacillus milk. Surgical measures fall under three general heads: (1) Rid the articulation of the products of inflammation. (2) Remove the hypertrophied villi and osteophytes which interfere with the functions of the joint and produce erosion of the articular surfaces, and (3) correct deformities.

Clinical and Post-Mortem Observations on the Status Lymphaticus.—Notes of five cases with full autopsy findings are given by R. E. Humphry, who says that the thymus gland so often enlarged in these cases often remains hidden at the root of the neck, partly covered by the inner extremities of the clavicles. In fatalities of this class it seems evident that it is the respiratory system that is first affected and not the heart, as is generally supposed. The author confesses that he does not know of any positive collection of signs or symptoms on which we can base a diagnosis of status lymphaticus. It may be that there is some change in the blood with which we are as yet unacquainted. Males are apparently more liable to the disease than females. Death may come without any apparent warning. Many fatalities have followed the use of ethyl chloride as a general anesthetic, and the author claims that this remedy is a valuable one and has been greatly maligned and he says that there is no evidence to show that it is any worse than any other anesthetic in dealing with the status lymphaticus. A practical point is the statement that if the region of the lingual tonsil shows a great excess of lymphoid tissue anesthetics should be avoided, for this lymphoid excess is suggestive of the general status lymphaticus. Unfortunately the negative aspect of this point is of no value.

British Medical Journal, December 26, 1908.

Pyrexia During the Puerperium.—L. B. Crane presents in tabulated form a study of the causes of fever in 1,196 consecutive cases of childbirth. Special points considered are (1) the number and percentage of cases of pyrexia, with relative frequency in primiparæ and multiparæ, (2) the usual time after delivery at which the normal limit is passed, (3) duration of pyrexia from all causes and of those cases clearly due to sapremia, (4) the range of temperature in primiparæ and multiparæ respectively, and (5) the more common causes and their relative frequency. Concerning the latter point the author says that careful clinical and histological researches show that most rises of temperature are due to the activity of pathogenic organisms. Out of the 1,196 cases, 24 per cent., of the pyrexias could be definitely traced to sapræmia in uterus, vagina, or perineum. In 36 per cent. of the cases there was constipation. Such sapræmia is probably due to some extent at least to imperfect drainage of the lochia. Constipation acts as the second great cause of fever. In 9 per cent. there was a "reaction" temperature by which is meant a transient rise unaccompanied by any corresponding rise in the pulse rate, which occurs only within twenty-four hours after delivery and rapidly falls again to the normal. This condition is found chiefly in primiparæ and is more frequent in summer than in winter. In 11 per cent. breast conditions were responsible for the fever; in 5.2 per cent. the respiratory organs; in 2.9 per cent. thrombosis, urinary, and dental causes, and in 0.6 per cent. emotional causes. This latter variety seems to be more common in maternity hospitals when they occur most frequently on visiting days. They are more frequent in primiparæ, especially in unmarried women. The fever may be high when the patient is awake and fall during sleep. Its recurrence is very rare. Slight elevation from emotional causes is more common than is generally believed and is often overlooked. Finally it must be remembered that pregnancy does not protect a woman from any disease to which she may be exposed and the possibility of such infection should always be considered in unraveling an obscure febrile movement.

Asthma.—A. G. Auld gives a general description of asthma, his sub-headings being historical note, recent anatomy and physiology, spasm or hyperæmia, action of amyl nitrite and adrenalin, pathological basis of the affection, and management. His choice of this last term rather than of the word treatment shows his broad conception of the condition and his relegation of drugs to their proper place in therapy. He says that the disease requires consistent and watchful care. No one plan is applicable to all cases. As to sedative drugs during acute paroxysms, we should always remember their tendency in numbing the nerve centers and rendering the bronchial mucosa insensitive to arrest or prevent those metabolic processes designed to rid the system of the asthma poison, and in addition there is the danger of the formation of a drug habit. Special organs always to be looked after are the nose, nasopharynx, and stomach. The lungs must be carefully ventilated. A regulated amount of hill-climbing is an excellent form of pulmonary exercise. Swimming is also an excellent exercise for asthmatics. It

increases the depth of breathing and brings into play the accessory muscles of respiration. It is also a tonic to the nervous system. All the emunctories must be kept in good working order. Overeating is to be avoided and all foods slow and difficult of solution in the stomach should be cut out. Vegetables producing flatulency are harmful. Cool water may be given freely. All carbonated beverages are to be avoided and as well strong drink of any kind.

Berliner klinische Wochenschrift, December 28, 1908.

Treatment of Pernicious Anemia.—Klemperer says that cholesterin has been introduced into the therapy of pernicious anemia because of Ransom's finding that it prevented the hemolytic effects of some substances, such as saponin and cobra poison. The objections to the use of cholesterin consist in the lack of evidence that pernicious anemia is due to hemolysis and in the fact that the substance is not at all decreased in the blood of these patients, but is often increased above the normal figures. Klemperer has at first attempted to administer cholesterin in three per cent. solution in oil, but this disagreed with most patients. The feeding of milk, cream and butter, however, accomplishes the same results by increasing the fat and the cholesterin content in the blood. Large amounts of these substances were used in the diet, and the results were very favorable, though it is impossible to say whether the cholesterin had anything to do with it. At the same time Klemperer used arsazetin, which proved to have a more favorable effect upon the blood formation than other preparations of arsenic.

Münchener medizinische Wochenschrift, December 22, 1908.

Cervical Ribs.—Schaefer says that cervical ribs are not at all so rare as has been thought previously; 139 cases have been described before 1894, and the use of x-rays since that date has shown that in many cases the presence of this anomaly has escaped attention. He has observed three cases of cervical ribs. The first patient was a woman whose affection wsa diagnosed as incipient pulmonary tuberculosis. The ribs in her case simulated very closely enlarged cervical lymphatic nodes, and the apices showed diminution of resonance on percussion. X-ray picture proved the existence of the anomaly. The other three cases were likewise sent in with the diagnosis of pulmonary tuberculosis founded upon the physical signs obtained in the examination of the apices. Two of them showed some respiratory symptoms of pulmonary tuberculosis, but in no proportion to the great real of dullness due to the presence of the ribs. The third case was not tubercuolus at all, the diagnosis of tuberculous infection of the lymph nodes being founded simply on the signs given by the rib. Schaefer lays stress upon the necessity of remembering the possible presence of this anomaly when examining the lungs for signs of early tuberculosis.

Treatment of Suppurations.—Kolaczek says that the pus of tuberculous abscesses and of those caused by pyogenic cocci is quite different in character, the former being very poor in ferments while the latter has an abundance of them. While the introduction of leucocytes or some substances that would cause the gathering of leucocytes in the diseased focus has a very favorable effect upon the course of tuberculous affections, the opposite method, that is, the use of anti-ferments, is the best in acute suppurations. Blood serum or the fluid of ascites or of a hydrocele can be used in this way, and in certain conditions where these are not obtainable the serum of animals may likewise be employed. The anti-ferment content of the latter may be raised by immunizing the animal by injections of ferments. The abscesses may be simply punctured and then filled with the serum, or in other cases incised and washed out with the serum. The curative action of the serum is explained by the inhibition of the dissolving action of the ferments contained in the pus of abscesses, by the diminution of intoxication of the organism because of lessened destruction of tissue by the action of ferments, and by the anti-bacterial effect of the serum.

The Value of Blood Examinations in Surgery.—Fabian says that the morphological examination of the blood is of no less value for surgeons than a bacteriological study of this tissue. Especially important is such an examination in the presence of tumors of the lymph nodes. Thus pseudoleukemia may be diagnosed by the relative lymphocytosis and the increase in the number of large mononuclears; Hodgkin's disease may be suspected from the increase in the polynuclear neutrophiles; tuberculosis of the lymph nodes may be suspected if the number of the lymphocytes is diminished, and lymphosarcoma may be diagnosed in the absence of any typical blood changes. Another condition in which the examination of the blood may be of value is echinococcus cyst, which is often accompanied by an eosinophilia.

French and Italian Journals.

Hemorrhoids in the Child.—Denis G. Zesas states that, although hemorrhoids are rare in children, they do occur, forming bluish tumors about the anus. The author believes that one of the factors is heredity, there being an abnormal congenital thinness of the mucous membrane of the anorectal region. The vessels of this region participate in this thinness and they are unable to support the column of blood pressing against the walls of the hemorrhoidal veins. Constipation is an important factor in many cases, while in others a chronic diarrhea causes weakness of the walls. Tumors in the abdomen and enlarged liver are occasional causes of pressure on the veins. Infection may also be a cause, inoculation taking place from simple subsphincteric ulcers and excoriations of the anal region. Hemorrhoids present two forms, angioma and simple varix. Diagnosis presents no difficulty. Treatment is the same as in adults, the Miculicz operation giving the best results.—*Archives Générales de Chirurgie,* October 25, 1908.

Evolution and Treatment of Tuberculosis Among Syphilitics.—Emile Sergent tells us that syphilis and tuberculosis are frequently associated in the same subject. Syphilis constitutes a prime factor in causing tuberculosis both directly and indirectly. Directly a tuberculosis may be engrafted on a syphilitic laryngitis or tracheitis; indirectly, syphilis causes a condition of the system which predisposes the subject to the reception of the tubercle bacillus. This occurrence of tuberculosis in the syphilitic may take place in the early primary or in the secondary stage. There may be association of the two lesions in the same location, as when we have a hybrid lupus. Generally the soil is such that both conditions are engrafted on it at the same time. We may have local tuberculosis in syphilitics, or pulmonary tuberculosis in syphilitics, and either condition may be the primary one. The author believes that the contraction of syphilis by a tuberculous subject is not as serious as has been thought. Provided that the tuberculous subject is in a fair general condition, he may not be very severely affected by the syphilis. In all probability syphilis is a cause of many cases of fibrous or sclerotic pulmonary tuberculosis. Tuberculosis also occurs in heredo-syphilis in young subjects. In all cases except very late ones or very acute ones of tuberculosis, anti-syphilitic treatment benefits both the syphilis and the tuberculosis. It should be so administered as not to interfere with the digestion and not to cause sore mouth.—*La Presse Médicale,* October 14, 1908.

Cystalgia in Movable Kidney.—Ferdinando Gangitano gives the symptomatology of movable kidney as including all sorts of neuralgic pains in the lumbar, crural, and intercostal regions, gastralgia, hysterical attacks, nervous phenomena, abolition of reflexes, diminution of the visual field, and disturbances of the genital organs. The author records a case in which the disturbances of the bladder were very severe and of a neuralgic nature. The pyelo-uretero-vesical reflex was excited in this case. The nervous filaments become congested or affected by toxic elements and react excessively. The same plexus which supplies the bladder enervates the lower portion of the ureter. The pain resulting causes in the author's case a course of treatment for cystitis by means of lavage of the bladder to be undertaken. The reflex genital pains caused a curetting and other uterine treatment to be undertaken, all of which produced no benefit because the cause of all the trouble was a movable kidney. The pain was due to contractions of the detrusor and sphincter of the bladder, and with them was combined disturbance of micturition.—*La Riforma Medica,* October 26, 1908.

The Bactericidal Power of Living Cells.—A. Albergo-Berretta, after experiments on animals by injections of emulsions of bacteria to ascertain the power af the living cells to destroy bacterial life, gives us the following conclusions: That the uninjured tissues as long as they preserve their vital properties are able to destroy rapidly all microorganisms that come immediately in contact with them. The microorganisms only find a condition adapted to their action in the presence of injuries to the tissues, or in conditions in which their vitality is lowered. In this destruction the phagocytes take an important part, but they are not the only factor in this destruction of germs. There are substances already contained in the protoplasm of the tissues which kill the germs, and all cells have the power of elaborating such substances when they are needed. —*Lo Sperimentale,* July-August, 1908.

Book Reviews.

A Text-Book of Operative Surgery. Covering the Surgical Anatomy and Operative Technic Involved in the Operations of General Surgery. Designed for Practitioners and Students. By Warren Stone Bickham, M.D., Phar. M.; Junior Surgeon, Touro Hospital, New Orleans; late Surgeon to Manhattan State Hospital, New York; late Assistant Instructor in Operative Surgery, College of Physicians and Surgeons (Columbia University), New York; late Instructor in Surgery, New York Post-Graduate Medical School and Hospital; late Visiting Surgeon to Charity Hospital, New Orleans; late Demonstrator of Operative Surgery, Medical Department, Tulane University of Louisiana, New Orleans; Fellow of the New York Academy of Medicine, etc. Third edition, greatly enlarged; containing 854 illustrations. Philadelphia and London: W. B. Saunders Company, 1908.

The well-known text-book of Dr. Bickham appears in this edition enlarged by over two hundred pages of text and over three hundred illustrations. It has thus kept pace with the progress of surgical technique and remains one of the most complete one volume text-books on the subject. The consideration of each operation consists in a concise description of the results aimed at and in directions regarding the position of the patient, followed by the surgical anatomy of the parts and the external landmarks; the technique is then fully given from the first incision to the last suture closing the wound. Splendid illustrations, the work of Miss Fry and of Mrs. Farnham, help to fix the descriptions in the mind of the student and bring back to the operator the picture of the parts as he sees them in the living subject. The index is very serviceable, various technical procedures being entered both under their names and under the names of surgeons who have introduced the method. We have no hesitation in recommending the book as admirably adapted to the needs of students and practitioners.

Einfache Hülfsmittel zur Ausführung Bacteriologischer Untersuchungen. Von Dr. R. Abel, Geheimer Medizinalrat in Berlin, und Dr. M. Ficker, Professor in Berlin. 2 Auflage. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1908.

This is a booklet of fifty pages containing directions for fitting out a small bacteriological laboratory. The preparation of the usual culture media and stains is explained, and a list is given of the apparatus and material required. The book will prove of use to any one buying supplies for a small laboratory.

Emergency Surgery. For the General Practitioner. By John W. Sluss, A.M., M.D., Professor of Anatomy, Indiana University School of Medicine; formerly Professor of Anatomy and Clinical Surgery, Medical College of Indiana; Surgeon to the Indianapolis City Hospital; Surgeon to the City Dispensary; Member of the National Association of Military Surgeons. With 584 Illustrations, some of which are printed in colors. Philadelphia: P. Blakiston's Son & Co., 1908.

This is a handy volume bound in flexible leather and small enough to go into an overcoat pocket. It is meant for the general practitioner who does not refuse his services in surgical capacity, though he has not made a specialty of that branch of practice. Accordingly, the book is intensely practical; it tells the methods of administering anesthetics, of stopping hemorrhages, of preparing material, and finally of operating that the author has found most serviceable in his own practice. The dogmatic character of some directions is fully made up for by the clearness gained; references to literature are omitted because of the very aim of the book to give one or at most two methods of operating and no more. Most of the commoner operations are included in the scope of the book from a tracheotomy and a circumcision to an operation for hernia or a laparotomy for appendicitis. The treatment of fractures and dislocations is allotted sufficient space. The illustrations are good. We recommend the book as fulfilling the purpose of the writer, to furnish a manual of ready assistance in preparing for an emergency operation.

Syphilis Osseuse (Syphilis acquise). Par le Dr. Louis Spillmann, Professeur agregé à la Faculté de Médecine de Nancy. Avec. 21 figures, formant 12 planches hors texte. Paris: G. Steinheil, 1909.

This little monograph has been written under the direction of the well-known syphilidologist, Professor Fournier of Paris. After a short historical introduction the author considers the frequency, the mode of invasion, the localization and the etiology of the syphilitis diseases of bones. The latent, the acute inflammatory and the gummatous lesions are treated in their turn. One chapter is devoted to the clinical aspect of the subject and has many valuable hints for the diagnosis of the syphilitic affections of bones. Treatment is likewise considered. The twelve plates show the gross lesions of the disease.

The Surgery of the Ear. By Samuel J. Kopetzky, M.D. New York: Rebman Company, 1908.

This volume, while not all that the expectant reader hopes it will be when he opens it, nevertheless deserves to be read as an introduction to more complete treatises on the subject yet to be written. The author has not learned the art of balancing unimportant facts against those of indispensable value, and hence he places undue stress on certain indifferent points and passes over essentials with a mere word or two. For instance, his discussion of new growths is incomplete and unsatisfactory, being limited chiefly to the polypoid variety. Chondritis and perichondritis are not mentioned at all, and we do not find anything upon cosmetic surgery of the external ear. No reference is made to the use of blood examination as an aid in diagnosis, nor of skull fracture through the temporal bone with its important complications and sequelæ. The bacteriology of surgical conditions receives scant mention. As for illustrations, the four colored plates are very good, but the line drawings are crude and the artist has failed in many cases to grasp the meaning of what he is trying to show. There is great need of an exhaustive treatise on otological surgery and the author deserves thanks for blazing his way through the mass of material which has accumulated in the past decade. His failure to give us just what necessity demands is not entirely his own fault, but partly that of the unsettled condition of his subject.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles. By Leading Members of the Medical Profession throughout the World. Edited by W. T. Longcope, M.D., Philadelphia. Volume III, Eighteenth Series, 1908. Philadelphia and London: J. B. Lippincott Company, 1908.

The new number of this well-known quarterly contains articles on treatment, medicine, surgery, gynecology, pediatrics, orthopedics, psychiatry, neurology, ophthalmology, rhinology and pathology. The more valuable of these are: "Melanotic Neoplasms," by John H. Gibbon; "Treatment of Fractures by Internal Splints," by E. M. Corner; "On the Trail of the Subconscious," by Joseph Jastrow; "On Leukemic Retinitis," by A. Rochon-Davigneaud, and "Studies Upon the Etiology of Appendicitis," by Richard Kretz. In general the volume is as rich in practical and scientific information as its predecessors. It is illustrated by several photographs and by a colored plate.

Digestion et Nutrition, Apercus de médecine pratique, par le Dr. E. Monin, specialiste pour le tube digestif et la nutrition. Paris: Vigot Frères, 1908.

These observations in practical medicine are practical in the best sense, for Dr. Monin has brought to light the best that has been found in the management of the diseases which he here describes. No time is wasted in discussing this or that theory, but the author goes straight to the point and gives what the practitioner wishes to know. The chapter on gastric cancer is especially helpful, and the author's optimism in regard to palliation of the more distressing symptoms is especially pleasing, inasmuch as so little is ordinarily done for these patients. Nervous and acid dyspepsias, ulcer of the stomach, and alimentary poisoning receive due consideration, and the author has something to say about such diverse topics as floating kidney, rheumatism, gout, obesity, pyelonephritis, and diseases of the heart.

Ärztliche Beredsamkeit. Von Dr. med. Henry Hughes, Arzt in Bad Soden a. T. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1908.

The reviewer fails to see any use in this little book, which purports to analyze the usual conversation of the physician with his patients and to give model speeches for various occasions in the relations of these two persons. Indeed, it is even ludicrous to read a model little speech on the occasion of a patient's death or an exhortation to another patient to agree to an operation. The author's style shows him to be a well-read and entertaining writer. It is to be regretted that he should waste his time in writing such material as forms the subject of this little book on medical eloquence.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Twenty-first Annual Session, Held in St. Louis, December 15, 16, and 17, 1908.

THE PRESIDENT, DR. F. W. PARHAM, OF NEW ORLEANS, LA., IN THE CHAIR.

Syphilitic Hyperplasia of Bone.—Dr. C. E. CALDWELL of Cincinnati said that this conditon was characterized by the deposition, without apparent coincident inflammatory symptoms, of a bony substance from the osteogenetic layer of the periosteum. When occurring in the long bones, particularly in the tibia, it resulted in overgrowth or a species of gigantism of the affected bone. Occurring as it frequently did in the epiphyseal ends of the long bones, it might, through juxtaposition to a joint, be mistaken either for tuberculous epiphysitis or a myeloma of the epiphysis. Fortunately, in the Röntgen ray we had a very satisfactory means of differential diagnosis. The class of cases to which he referred had usually a remote and not always clearly defined history of syphilitic infection. The progress of the affection was so gradual and accompanied by such slight disturbance of the comfort of the patient that he did not usually present himself for treatment until the bony overgrowth was such as to attract his attention. Inasmuch as the cases which had come under the author's observation had not undergone operation, but had more or less promptly yielded to treatment with iodide of potassium in large doses in a period varyng from six weeks to three months, with local inunctions of mercurial ointment, there had been no opportunity for pathologico-histological investigation. Inferentially, from the *x*-ray pictures, there was a formative osteitis of chronic form, which might not inaptly be compared to the chronic interstitial hyperplasia of internal viscera, and to the syphilitic hyperplasia of the coats of arteries resulting in obliterating endarteritis. It was not at all improbable that in this class of cases there might be nutritive changes in the periosteum which produced a condition not dissimilar to leontiasis or to Paget's disease.

Dr. ARTHUR DEAN BEVAN of Chicago said he had had such an experience as this, that of a man brought to him by a good practitioner with a diagnosis of sarcoma of the thigh, the patient, the father of four or five healthy children, denying absolutely any history of syphilis, and when informed that amputation at the hip joint was necessary, was quite willing to submit to the operation. Fortunately, before deciding upon this extensive operation, massive doses of iodide of potassium were employed for a few months, with entire disappearance of the tumor, and then the patient confessed to a syphilitic lesion long before he was married, stating that he had not said so before because he was confident that there could not be any connection between that initial lesion and his present condition.

Myoma and Myosarcoma of Stomach.—Dr. JAMES E. THOMPSON of Galveston, Texas, reported one case with the following symptoms: Marked hematemesis and melena; muscular cramps (tetany); no tumor palpable. Examination of gastric juice showed free HCl, 40: no lactic acid. A partial gastrectomy was performed successfully. The tumor was found to spring from the anterior wall of the stomach, and projected into the interior. Microscopically, it was a pure myoma.

Dr. MAURICE H. RICHARDSON of Boston had been unable to tell the difference between a malignant tumor of the pylorus and a chronic ulcer at the time of operation. The surgeon could not always have at hand an expert microscopist, with freezing apparatus, etc., to aid him, and yet he must know on the spot what the diagnosis was.

Dr. CHARLES H. MAYO of Rochester, Minn., said benign tumors of the stomach were so rare as compared to malignant that they were very seldom thought of; at the same time, there were quite a few of them in which the tumors had been found to be malignant at autopsy.

Dr. GEORGE W. CRILE of Cleveland added a case of myoma of the stomach which was operated on by his associate, Dr. Lower. He also reported a case of adenomyoma, which was situated in the wall of the stomach, but at the time of operation it was supposed to be a sarcoma.

Conclusions Based Upon Observations of Five Hundred Cases of Fracture of the Skull.—Dr. WALTER C. G. KIRCHNER of St. Louis read this paper: Linear fractures of the vault usually did not require operation unless they involved important vessels or sinuses. In depressed fractures the fragments causing depression should be elevated or removed. Experience had shown that in compound fractures, especially where there was injury to the dura or brain, drainage of the wound was usually desirable. Operation for fracture at the base was indicated where hemorrhage was extradural and where there were no signs of compression. The middle fossa was most frequently involved and drainage here could be easily instituted. The practice of examining hematomata by means of exploratory incision was practically without danger, when reasonable precautions were taken, and often gave most valuable information as an aid in diagnosis. The neurological findings were of value in determining focal symptoms, but when complex brain disturbances existed, they might be unreliable as diagnostic aids and required special interpretation. Brain compression was a positive indication for operation, and, as a rule, the sooner compression was removed, the better the prognosis. At operation shock and hemorrhage were factors that should be carefully regarded, and operation should be done as speedily as possible. In doubtful cases, where it was probable that the symptoms were caused by brain compression, exploratory operations were indicated. The expectant treatment was to be advocated in those cases in which there were no symptoms of brain compression, in which the temperature and pulse remained nearly normal, and in which the reflexes were but little altered. Unconsciousness in itself was no index of the seriousness of the trouble. Operation was contraindicated in those cases in which the symptoms were the result of intrinsic destruction of brain tissue, when the temperature was high, where the pulse was rapid, and the blood pressure diminished. The importance of a longer period of rest in bed should be strongly emphasized, so that the danger of secondary complications might be avoided.

Fractures of the Elbow Joint.—Dr. ROBERT CAROTHERS of Cincinnati selected three points for consideration: (1) The importance of a correct diagnosis; (2) correct apposition and maintenance of the fragments, and (3) early passive motion. A diagnosis was based upon the physical signs present and confirmed by *x*-ray plates made at right angles to each other of the injured elbow. It was the careful study of the case that counted. The cause of the accident, the age, comparison of the injured with the uninjured elbow, and then an elucidation of any and all the signs of fracture were considered, especially as applied to the location under discussion. After this evidence had been obtained, with a careful study of the *x*-ray plates, one was able to arrive at a diagnosis which which was not only complete, but scientific. Since these injuries occurred with such frequency in childhood, in reading an *x*-ray plate in such a case one must have in mind the ossifying centers in the immediate neighborhood of the elbow joint, and not be misled thereby. He could not lay enough stress on the *x*-ray examination of fractured elbow joints, for a diagnosis otherwise made was a guess at best. The most frequent fractures of the elbow

joint were pointed out, and their treatment discussed. In the so-called chisel fractures of the head of the radius the repair was usually with so much callus and impairment of function of the joint that it was advisable, unless for some good reason contraindicated, to remove the broken fragment. In the fractures of the neck of the radius, the best results would be obtained by making apposition, which ordinarily was easy by manipulation and maintaining the same with the forearm in a semiflexed position to overcome a possible displacement of the biceps.

Suprapubic Prostatectomy.—Dr. ARTHUR DEAN BEVAN of Chicago said that suprapubic enucleation of the prostate had the widest field of usefulness. It was practically applicable to all cases of prostatic hypertrophy, in which a prostatectomy was indicated. It gave full and complete information of not only the prostate, but the bladder and its contents. It did not injure or interfere with the musculature and nerve supply of the perineum and structures controlling continence. It carried with it little risk of injury to the rectum; it was seldom followed by incontinence, fistula or stricture. The disadvantages claimed against it were greater mortality and necessity of longer residence in hospital. He felt confident that there were fewer complications after the suprapubic than after the perineal operation. This operation was preferable to other methods which had been advocated.

Dermoid Cyst of the Kidney.—Dr. WILLIAM S. GOLDSMITH of Atlanta, Ga., said that only two cases of dermoid cyst of the kidney had been reported up to this time, one by Paget, in 1853, and the other by Haeckel, in 1902. The symptoms in the author's case were those of a solid tumor of the kidney, probably the malignant type. It was of slow growth and associated with it were hematuria, pain, and tumor. The patient, aged 20, family history negative, at two years of age suffered with pain in the right lumbar region, and at intervals of two or three years was treated for kidney trouble. When sixteen years old, he experienced the beginning of a dull pain in the right side, which progressively increased until two weeks ago, when the pressure and pain radius was compared with that of a heavy watch lying in the abdomen. Four years ago he had attacks of colic, followed by a slight hematuria. These attacks confined him to the house for twenty-four hours, and were relieved by hypodermics of morphine. Recurrences took place two or three months apart, and for the past two years were characterized by the appearance of a solid tumor, which presented in the right lumbar region. Hematuria and great pain were also accompanying features, and the disappearance of the outline of the tumor was frequently followed by a cessation of the pain. Having witnessed an attack three days before the operation, when the tumor was most manifest, he was convinced that these symptoms were due to a twisted ureter, since the return of the kidney to its normal position practically obliterated the tumor outline. Twenty-four collections of urine showed insignificant deviations from the normal quantity, and microscopical and chemical examinations were negative, except for red blood cells. The patient's weight was normal, and his general condition good. An exploratory operation was advised and consented to. A lumbar incision was made, which exposed a large semisolid tumor of the upper pole of the kidney. Efforts to deliver the kidney resulted in a rupture of the tumor, and a quantity of red granular material was scooped out with the fingers. Nephrectomy was quickly performed, and recovery was prompt and uneventful. A pathologist pronounced the tumor to be a dermoid cyst.

Stone in the Kidney.—Dr. MAURICE H. RICHARDSON of Boston said that operations for stone in the kidney and ureter were becoming of greater frequency and importance. In early and difficult cases the diagnosis rested upon a history of pain in some of its forms, usually without confirmation by the *x*-ray, cystoscopy, or ureteral catheterization, by the touch, or by marked signs in the urine. The history in such cases, as in many gallstone cases, gave the only clew; hence we should study with renewed care the history of stones demonstrated in kidney or ureter, just as we did the history of stones demonstrated in the gallbladder. The indications for operation were hopeless impaction of a stone in the ureter, in the kidney the mere presence of a stone. The contraindications were local lesions which either forbade operation or made it so dangerous or so uncertain that the patient had much to lose and little to gain. The great operative danger in nephrotomy, as well as nephrectomy, was hemorrhage; and when this was from the renal artery or vein or vena cava, easy and instant accessibility was essential to avert death on the table; hence the anterolateral approach was the best. Nephrectomy was unjustifiable unless the changes in the kidney demanded it, especially when the remaining kidney was so likely to contain the nuclei of stones. Before a nephrectomy was done, the remaining kidney should be very carefully palpated by the hands. As a stone may be overlooked, so may tuberculosis or other infections.

Conservative Surgery, Then and Now.—Dr. F. W. PARHAM, the President, selected this title for his Presidential Address. The aggressive surgeon, who always felt sure he was right and then went ahead, would do well to temper the enthusiasm born of the present brilliant achievements of surgery by giving reverent heed to the admonitions of the past. In renal surgery conservative and radical surgery displayed most conspicuously their coincidence. Here results demonstrated that often the most conservative treatment was also the most radical. The glory of the present-day surgery rested primarily upon more accurate diagnosis, but the refinements of scientific investigation must always be subjected to the criticism of common sense. It was becoming more and more characteristic of the modern surgeon that, while recognizing the value of data furnished him by the laboratory, he would relentlessly subject them all to the test of reason and would only decide upon his surgical therapeusis when, after a thorough study of all the facts, he had obtained a true perspective of the case.

Appendicostomy in Pernicious Anemia.—Dr. L. E. BURCH of Nashville reported this case, the patient being a negro, forty-five years of age. He concluded by saying that all cases should have the stools examined, in order to determine the presence of infection by *Bacillus capsulatus aërogenes*. If these bacteria were present in great numbers, then high irrigation, combined with arsenic internally, should be used, and if the patient failed to improve, the appendix offered the best route for thorough irrigation.

Dr. H. S. MCLEAN of Richmond, Va., said that twenty months ago he operated in a similar case. The man had been ill for years. He was brought with an acute attack of catarrhal appendicitis, and the history disclosed anemia, continued weakness, and bowel trouble. The speaker performed appendicostomy. The patient had been living on zwieback, buttermilk, and the like for years, but six weeks after operation the red blood count was over four million. He soon gained fifteen pounds, went to Europe, and was now in excellent health.

Porro-Cesarean Section.—Dr. F. D SMYTHE of Memphis reported a case in which he did this operation, and gave his reasons for doing so. The rapidity with which the Porro could be performed increased the chances of the patient surviving the operation. The patient was in a condition too much weakened to be subjected to any available risk of the puerperium, hence the Porro. There would always occur cases demanding cesarean section in the interest of the child and mother. In elective cases there should be no infant mortality attending either operation; hence the surgeon should select the operation that sub-

jected the mother to the least risk of losing her life. The author was fully convinced that the Porro operation was the safer, and that the surgeon performing the Sanger operation in an honest effort to preserve the reproductive organs, would have occasion to congratulate himself now and then on the result of his efforts in that plausible undertaking, but he could not escape the responsibility of the loss of a mother at times, whose life could have been saved had the simpler and safer operation been selected at the outset.

Elective Cesarean Section.—Dr. Miles F. Porter of Fort Wayne, Ind., discussed cesarean section as an operation of choice, especially in those cases in which delivery was usually effected by so-called minor operations or by unaided natural forces after long labor. Summarizing the reports of 126 elective cesarean sections collected by personal correspondence, the maternal mortality was found to be 1.58 per cent.; the fetal mortality, 0; the maternal morbidity, 12.69 per cent.; the fetal morbidity, 0. It should not be forgotten that the fetal morbidity following forceps, etc., was often worse than death. No method of delivery entailed so little risk to the child as did cesarean section. Remote ulterior results of cesarean section, including hernia, rupture of the uterus, and adhesions, could be so nearly prevented by proper technique as to render the dangers arising therefrom practically *nil*.

Necessity of a Second Operation for the Removal of the Appendix in Cases Where an Appendiceal Abscess Has Been Treated by Simple Incision and Drainage.—Dr. Stuart McGuire of Richmond, Va., supplemented a paper read by him in November, 1907, in which he discussed the necessity of a second operation for the removal of the appendix after simple incision and drainage of an appendical abscess. Among the cases reported in the former paper, there were 23 cases of appendical abscess of the class adherent to the parietal peritoneum. In this group the treatment had been simple incision and drainage, no effort being made to locate or remove the diseased appendix. In every instance the patients were told that the operation was not for appendicitis, but for an abscess which was the result of appendicitis, and that the appendix had not been removed. To reach conclusions, two methods of investigation were followed; first, the opinions and practices of a number of eminent surgeons were obtained, and, second, the twenty-three patients whose cases were reported were written to and their subsequent histories ascertained. Dr. McGuire quoted the opinions of the twenty-six surgeons responding to the inquiry, and from the two lines of investigation drew the following conclusions: While a surgeon might be justified in advising a secondary operation in all cases as theoretically the safest plan to follow, he was not justified in persuading, urging, or starving a patient until he consented to have it done. The appendix should always be removed at the first operation, if the abscess was small, and not adherent to the abdominal wall beneath the incision. It should be left only in neglected cases, where the abscess was large and attached to the parietal peritoneum. When this condition existed, the appendix was usually gangrenous, underwent liquefaction, and was eliminated with the discharges. In such cases suppuration continued, as a rule, for several weeks, and before a secondary operation could safely be done, the patient was homesick, weakened physically by confinement, and depleted financially by the expenses incident to his stay in the hospital. Experience showed that if subsequent trouble developed, the infection was not usually acute, and pus, if it were formed, was walled in by old adhesions. Therefore, the surgeon did his duty if he made it clear to the patient that, owing to the complications which existed, it was not found safe to remove the appendix, and told him that while a second operation was advisable, it was not imperative unless he had tenderness over the incision, colicky pains in the bowels, or persistent digestive disturbances, in any of which instances it was distinctly necessary for him to seek promptly surgical assistance.

Resection of the Bowel, with a Report of Eleven Cases.—Dr. J. Shelton Horsley of Richmond, Va., first discussed the technique of the operation and described the advantages of a continuous right-angle suture penetrating all coats over interrupted sutures and mechanical appliances. In order to have satisfactory union, there must not only be approximation of the serous coats of the bowel, but a mild degree of pressure as well, and this pressure must be uniform along the line of sutures. Experiments showed that mere approximation of the peritoneal coat in dogs did not always secure union. In resecting the bowel, he first divided the mesenteric border and clamped and ligated this area before opening the lumen of the bowel. Union was made by a continuous suture inserted in the following manner: Starting about one inch from the mesenteric border, a mattress suture was inserted, so that the knot was on the mucous membrane in the manner advocated by Connell. The short end of this suture was clamped and the needle with the long end made a continuous mattress suture toward the mesentery. After one-third of the bowel was approximated in this manner, the needle was brought through on to the peritoneal surface and the rest of the union was effected by a continuous right-angle suture penetrating all coats. When the point where the original knot was tied was reached, the suture was terminated by tying the thread to the short end of this knot. This made practically one knot for the whole line of sutures and brought this knot within the lumen. Of the eleven cases reported, there was only one death. This was in a patient with strangulated hernia who had been a chronic alcoholic for years. The post-mortem showed no sign of leakage or peritoneal inflammation. Death was evidently due to suppression of the liver and kidney functions. There were 12 resections in the 11 cases, as in one patient a double resection was necessary. The operations included five resections in four patients for strangulated hernia, one for gangrene from a band, one for volvulus of the sigmoid, two for malignant disease of the large intestines, one for tuberculosis of the cecum, and two for damaged intestine during pelvic operations.

Obstruction of the Bowels.—Dr. T. C. Witherspoon of Butte, Mont., said that after reflecting upon the results he had obtain in 36 cases, with seven deaths, of bowel obstruction, he was prepared to go to less extreme measures to bring about relief than formerly. Most surgeons were inclined to look too much to the mechanical side of the problem and neglect the physiological. Even in strangulation by a hernial ring, the lumen of the bowel loop caught in the hernia did not suffer from complete closure, but rather was there a vascular obstruction. The bowel shut-off was as complete when its coat died from a thrombotic process as when it was caught in a hernial ring. The real obstruction was one of function and not of pure mechanics. The danger to the patient arose from toxic absorption proximal to the affected segment. With this in view, he had formulated for himself the cardinal principle of bowel drainage. The method of obtaining this might vary as the conditions varied, but it was the part of wisdom never to tax the patient's strength by long procedures except in the few instances, like a Mechel's diverticulum strangulation. If the condition was due to a band, invagination, hernia, or the like, which admitted of easy remedying, the method should be applied, but if the case was one of uncertainty or necessitated an exhaustive and dangerous procedure, it was always better to let out the proximal bowel contents by an artificial opening until the general toxic state was much improved, when a more radical measure might be adopted to bring permanent relief. Inflammatory obstructions cleared up beautifully when the

loop proximal to the involved segment was drained. Neoplastic or granulomatous processes might be readily handled after sufficient drainage was given the bowel above the lesion. The danger lay in attempting a complete procedure at the one time. Why should one attempt to resect the bowel in a very ill patient when a strangulated hernia existed? A simple local anesthetic opening would suffice to bring about relief from sufferings, physical and toxic. In a week the anastomosis became a matter of simple surgery. In one of his patients, a child of 12 years, obstruction became complete nearly three weeks after an operation for general peritonitis. He opened the abdomen only to find a conglomeration of bowel loops, which to unravel would have probably caused death. He selected a portion of bowel which, because of its distention was recognized as proximal to the obstruction, and which, at the same time, seemed to be the most distal distended loop from the stomach. This was drained through a large rubber tube. In less than two weeks the fecal movements were passing again by the natural route and the artificial opening was allowed to close. Again, in the treatment for obstruction, success lay in seeking to drain rather than to unravel the mechanical difficulty. When the latter could be done without adding a material chance to mortality, it was wise to adopt the measure, but when one added to the danger of the condition by so doing, he should simply drain artificially and at a later time a serious condition would have become simple.

Penetrating Wounds of the Abdomen.—Dr. Floyd W. McRae of Atlanta, Ga., said that of his fifteen cases, nine had the benefit of early operation with seven recoveries. Seven of the nine operations were for rifle or pistol-shot wounds, and all presented grave visceral injuries. One had an extensive laceration of the liver, with excessive hemorrhage; the patient, exsanguinated, and pulseless at the wrist, recovered. One had three perforations in the stomach, with leakage; recovery. Three had multiple perforations in the small intestines, with leakage in all; two recoveries, two deaths. In one of the above the bladder was also injured, but recovery ensued. Two operations were done for stab wounds of the liver. Free hemorrhage in both cases was controlled by suture of the liver wounds and gauze packing. Both recovered. He had treated four pistol-shot wounds of the abdomen expectantly, with three deaths and one recovery. One man with a stab wound, treated expectantly, died. Of five cases, there were four deaths, one recovery. He had done two late operations for complications due to penetrating wounds, that might have been prevented by early operation; both died, a mortality of 100 per cent. The above statistics, his personal experience, observation, and a careful review of the literature on penetrating wounds of the abdomen, led him to make the following conclusions as to civil practice: 1. In civil practice every suspected penetrating wound of the abdomen, under favorable conditions of practice, should have the benefit of wound tracing. 2. When the wound proved to be penetrating, an exploratory laparotomy should be done at once and visceral damage excluded or repaired so far as practicable. 3. There was far less danger from wound tracing than there was from probing or from masterly inactivity, while awaiting positive evidence of visceral damage requiring operative interference. 4. Local toilet with moist sponging for cleansing was better than free peritoneal irrigation. 5. When in doubt, it was safer to drain. 6. Operations done within two hours should not give a mortality over 25 to 30 per cent.; within four hours, over 40 per cent.; within six hours, over 50 per cent.; within eight hours, over 60 per cent., and within twelve hours, over 70 per cent. 7. After twelve hours, expectant treatment was best unless there was some definite indication for operation. These deductions did not apply to military practice.

Some Rare Forms of Hematoma.—Dr. J. Garland Sherrill of Louisville, Ky., reported three cases of hematoma presenting symptoms somewhat in common and extending beyond the usual time which these conditions lasted, one having existed for more than ten years, and each of them continuing to increase in size from the beginning. The following hypotheses were offered as possibilities in explanation of this condition: 1. The blood might flow through a sac returning into the vessel and remain fluid, at least in part, just as is the case in aneurysm. This proposition would seem to be fallacious because these hemorrhages were probably venous, and the tendency of a vein was to collapse immediately upon injury, and, moreover, no such patent vein had been noted in any of these cases. 2. The cellular tissues possessed the power of secreting a substance which tended to prevent coagulation. This seemed clearly refuted because the infrequency of the occurrence of persistent hematoma would appear to prove the lack of such power of secretion. 3. That slight infection present in insufficient amount to produce suppuration resulted in such change that the blood could not be taken up by the absorbent vessels. This theory seemed to the author to be irreconcilable to the facts in the case, for effused blood had but little power of resistance, and any culture of bacteria should find here an excellent pabulum, and suppuration would be inevitable. 4. That the tissues about a hematoma might be so dense or so compressed that the absorbent vessels would be occluded or obliterated, thus preventing the accomplishment of their normal functions. This proposition seemed to the writer to have a more probable foundation in fact, although not accounting fully for the phenomena. 5. That coagulation took place, but when disintegration occurred the blood remained fluid, but was not absorbable. This contention seemed also within the range of probability. 6. The constant escape of fresh blood occurred in a quantity sufficient to more than make up for the loss in volume from absorption. In proof of this the author believed it could be demonstrated that the escape of fluid into a hematoma did occur, as was shown in his cases, in which the tumor increased in size steadily. In one the bleeding occurred from a wounded vessel in the femur; in another, the source of the blood could not be discovered, but he thought it came from a small vein. There was also the possibility of blood being manufactured inside the sac, as in the case of the development of the circulatory apparatus in the embryo, although to use it seemed highly improbable that this could occur in adult life. From the evidence at hand, the author concluded that the tissues about a hematoma from pressure lost their power of absorption; that even though coagulation and disintegration occurred, resorption did not result, and that in some instances there was a continual addition to the amount of blood in the sac by an outflux from the damaged vessel.

Observations on the Surgical Treatment of Exophthalmic Goiter.—Dr. John R. Wathen of Louisville, Ky., stated that preliminary ligation of the superior thyroid artery on one or both sides had not only better prepared the patient to withstand the more severe shock of thyroidectomy, but had also greatly reduced the size of the tumor in the otherwise hopeless cases, and he had had occasion to employ to great advantage this method in several of his worst cases. In the preparation of the patient for operation he had tried almost every remedy usually recommended to reduce the pulse and better the condition, but none had yielded such good results as absolute rest in bed and tincture of strophanthus. It was that class of cases where no preliminary treatment seemed to be able to make such temporary reduction which were especially dangerous. These usually had an irregular pulse, a degenerated heart muscle, low blood pressure in contradistinction to the majority which had often a very much in-

creased blood pressure, albumen in the urine, or enlargement and fatty degeneration of the liver. Aside from the proper selection and preparation of the case, the most important thing was a rapid and safe technique suitable to the average surgeon and not a variety of complicated methods. The technique employed in his last fifteen cases had been a slight departure from that usually recommended. With the head elevated in the reverse Trendelenburg position, and a large sand pillow under the shoulders and neck, the skin was grasped with two pair of forceps in the median line and traction made upward. With the blunt-pointed scissors, instead of a knife, the skin and platysma muscle were incised, then with constant upward traction the incision was continued around the neck as far as was needed, using the scissors without in any way injuring the deeper structures. Next were ligated the anterior veins and the ribbon muscles of the neck, severed high up and retracted, then the capsule opened, and the tumor grasped with a stout pair of large volsella forceps, and traction made in an upward and opposite direction. This readily allowed the operator to wipe off the capsule of the gland with a piece of gauze, and placed the arteries and the veins to be ligated on the stretch. Forceps should always be used to clamp rapidly, and these could be placed close upon the tumor and ligated later with catgut after the complete enucleation. The isthmus was clamped with a large pair of forceps and cut V-shaped, parallel with the clamp, so that the raw edges could be turned inward by whipping over with catgut. The wound should only be washed out with hot saline solution, and closed with a subcuticular catgut suture. Drainage through a lower stab wound with large open rubber tube, instead of gauze or a cigarette drain, should complete the operation.

Consideration of the Mortality in One Thousand Operations for Goiter.—Dr. Charles H. Mayo of Rochester, Minn., said the mortality from early operations was high for the number operated, as the operations were performed from great necessity after the delay of long and oft-changed medication. Operations upon colloid, simple or diffuse adenomata, as a rule, involved slight risk to life. In his series of cases he had 574 of simple, colloid, or diffuse adenomata, treated by extirpation or enucleation, with four deaths; 18 malignant, with one death; 97 cases of hyperthyroidism treated by double ligation of the superior thyroid arteries and veins, with one death, and 15 cases with single ligation, with no deaths; 295 cases where more or less of the gland was removed, with 18 deaths, seven of which were in the first 46 cases.

Hypoplasia in Its Relation to Health and Disease.—Dr. Charles P. Noble of Philadelphia said that man consisted of a body and intellect and a moral nature, and might degenerate in either one or all three of his natures, and this degeneracy might be inherited or acquired. If the potential of life received by the ovum was imperfect, there resulted an imperfect body. The effects might be most marked in the physical body, in the intellect, or in the moral nature. When the potential of life was deficient, there resulted imperfect evolution and an imperfect adult; that is, the adult was imperfectly developed in all his parts —bones, muscles, circulatory apparatus, nervous system, ligaments, fasciæ—in other words, man was suffering from hypoplasia or imperfect development. The same conditions in kind, if not in degree, might be brought about by environment, malnutrition, insanitary conditions of living, traumatisms, or intercurrent diseases which acted by arresting development, that is, by causing hypoplasia. If the potential of life received in the ovum was very defective, there resulted embryonal or fetal death and abortion. In other cases there resulted monsters or instances of imperfect development, such as spina bifida, cleft palate, etc. There resulted idiocy, imbecility, and insanity of hereditary type, or the lesser degrees of what had heretofore been called functional nervous diseases or the symptoms complex, such as epilepsy, catalepsy, hysteria, nervous instability, and a tendency to the development of nervous prostration. In infancy and childhood there resulted a tendency to nutritional diseases which, acting as environment, tended to arrest normal evolution or development. In certain cases chlorosis followed, due to hypoplasia of the circulatory apparatus and the blood-making organs. Puberty was delayed, and in a woman menstruation was abnormal and painful. The young adult and the adult through imperfect development might retain the body form of the child, that is, neuter. This was the body form of the consumptive. The vertebral column did not retain its normal curves; the chest was flattened, and the abdomen protuberant, and, owing to the imperfect development, the hypoplasia of the ligaments and the muscles, the attitude of the man, was such that, as it is said, he looked as though he was tied together with yarn string. There resulted a loss of relative immunity, and so when we contrasted the diseases of civilized man with those of the savage, we found there was a tendency to the so-called surgical infections, including puerperal sepsis, appendicitis, tuberculosis, etc. There resulted a tendency to visceral ptoses due to the imperfect development of the ligaments of these organs and to the insufficient support of the abdominal muscles. This explained the failure to relieve the symptoms when such cases were operated on; whereas, when the cases of acquired ptoses in normal individuals were operated upon, the local diseases were cured and the patients got well. There resulted imperfect function of the glandular cells of the body, with consequent imperfect digestion, so-called nervous dyspepsia, when this was not acquired from environment. There resulted nervous instability, hysteria, catalepsy, epilepsy, insanity, idiocy, etc., which were but the manifestations of the various degrees of imperfection in the development of the nervous system, and these symptoms complex bore the same relations to hypoplasia of the central nervous system as a cough did to a bronchitis. Degenerates or defectives were the weaklings, the unfit, and the process whereby nature got rid of them was through progressive degeneracy until they lost the power of generation or deliberately refused to exercise it. In medicine this biological principle and the recognition of its results upon the body in the arrest of development would make simple things heretofore obscure, and would make prognosis and treatment rational instead of guesswork, as they had been. These patients, when afflicted with diseases, were different from normal individuals. When the local condition was cured in a normal individual, the patient was well; whereas in the defective, when the local trouble was cured, he still had hypoplasia, and so might retain the most of his symptoms. The greatest hope in the future lay in prevention. Through state medicine and through individual prophylaxis, the children of defectives and those who acquired hypoplasia must not be brought up under the usual environment. They must not be sent to school in the usual way, but must be sent to the country and live according to the laws of nature, whereby their development may become as perfect as is possible under the conditions. These people were the weaklings and could not stand the strains and stresses of life, and when subjected to them they always gave out and got nervous prostration. Therefore, the physician in dealing with these people should first treat them along lines of rest and improve their nutrition, and then must show that they could not perform the usual labor of other people, but must accept this as a fact and limit the expenditure of their energy to that which they manufactured. They could never do the full work of a normal man or woman.

Surgery of the Pleura.—Dr. John B. Murphy of Chicago said that pneumothorax was not so dangerous a condition as was formerly believed. In discussing lesions of

the pleura, one should first consider the primary infective, perforative lesion, which demanded prompt and immediate action; second, chronic indurated lesions, which called for masterly inactivity, so far as operations were concerned. In the first class of cases the use of the exploring needle between the ribs will usually afford relief; but incision would give these patients immediate relief. Aspiration did not cure chronic conditions of the pleura. According to statistics, of one thousand cases treated by simple aspiration, there were only two cures reported. In the suppurative types of infection of the pleura, absorption of the toxic products could be stopped, sterilization of the fluid effected, and the necessity for opening the chest avoided. A number of agents had been used for this purpose. Perchloride of mercury had been used with success. Formalin, which has little or no toxic effect, had great sterilizing power. In the other variety of cases, in which there was a dense, firm mass of cicatricial tissue, which would not contract, we had a different condition. This tissue would remain for years without absorption because many times it had large deposits of calcium salt in it and could not collapse. In these cases one could make use of the same injections, but they must be given more slowly. The injection of formalin and vaseline sterilized the fluid contents and prepared it for absorption, and finally in six months thereafter we would have a sanguinolent fluid, and in twelve months the patient was practically well without having any tube in his side.

Splenectomy for Splenomegaly of Doubtful Classification.—Dr. M. C. McGANNON of Nashville, Tenn., read a paper with this title, and reported a case of splenectomy. The case presented some unusual features not heretofore recorded in connection with primary splenomegaly. The patient was a white woman, aged 43. Chronicity was doubtful, since the patient first noticed the enlargement of the spleen only a few months before she came under the author's observation. Her physical condition had been below par for a year or two; but preceding an attack of pneumonia, which was four months before she discovered the splenic enlargement, she had not considered herself in any sense a sick woman. Anemia, hematemesis, jaundice, liver enlargement, all terminal symptoms, might have arisen later had the disease been permitted to continue. The most marked and unusual features of the case were the general enlargement of the superficial lymph nodes and the myxedematous symptoms; thickened, puffy skin, and mental hebetude, with complete disappearance of all symptoms and pathological conditions in other tissues after the removal of the spleen.

Relation of Surgery to the Neuroses, with Special Reference to Neurasthenia.— Dr. CHARLES M. ROSSER of Dallas, Texas, said that surgery was the most definite art with which medicine was concerned, and neurasthenia the most vague of diseases. Writers mentioned heredity and exercise, but ignored intercurrent causes independent of which, in many cases, physiology would not be disturbed, on account of predisposition and excitation. Neurasthenia was both a psychosis and a physical condition, and might be induced by surgical conditions which disfigured, disabled, or caused distress. As physical causes, deformities which might not affect vital functions, but which embarrassed sensitive temperaments, were factors. Extensive scarring from burns upon exposed surfaces was prevented by surgical skin grafting. Goiter, through visual and secretory disturbances, might cause stomach conditions that were amenable to surgery by digestive deviations and those disorders of the bile passages, as was true of chronic appendical involvement, which tended toward autointoxication, and insomnia was the most frequent forerunner of mental depression. The clinical examination should be as careful as though the symptoms were not exaggerated. The prognosis should be more guarded, but the patient should not be denied opportunity of physical relief on account of nervous and mental conditions, and should be subjected to no procedure that was not justified by clinical findings. The patients should always have the benefit of all doubts that were reasonable.

Fibroid Tumors and Pregnancy.—Dr. CHARLES L. BONIFIELD of Cincinnati pointed out that fibroid tumors of the uterus were said to be the penalty a woman paid for celibacy. All observers agreed that they were much oftener seen in women who had not borne children than in those who had, and one could safely say that sterility predisposed to fibroids, and that fibroids predisposed to sterility. Fibroid tumors had a tendency to render women sterile in three ways: First, the hypertrophic endometritis they produced rendered the endometrium unfit to receive and nourish the ovum. The nearer the fibroid was to the endometrium, the more marked its effect on this membrane. Second, they were frequently complicated by, and apparently caused, disease of the appendages, which prevented conception. Third, they might so displace the cervix that it was not bathed in seminal fluid during the sexual act. But as a fibroid might exist without producing any of these conditions, and as pregnancy might occur in spite of the presence of one or more of them, the coexistence of fibroid tumors and pregnancy was by no means extremely rare. It was probably more frequent now than formerly, for the reason that women were marrying later in life, and thus putting off their child-bearing until they had reached the age when fibroids were prone to develop. Pregnancy by the physiological hyperemia of the uterus to which it gave rise usually caused fibroids to grow rapidly. During the process of involution, following the normal termination of pregnancy, fibroids might decrease in size very perceptibly. Cases had been reported where they had disappeared entirely. Fibroid tumors might have little or no effect on pregnancy, or might give rise to the most serious complications. Submucous fibroids might cause the premature expulsion of the ovum. Pregnancy might go to term and labor might be normal, but followed by severe hemorrhages, the fibroid acting as a foreign body in the uterus and preventing normal contraction and retraction of the muscular fibers. The efforts of the uterus to expel the fibroids might be successful. There was danger in such a case if the fibroid be attached near the fundus, that inversion might follow the expulsion, for if a fibroid had developed between the folds of the broad ligament, it might prevent the uterus from rising into the abdomen as pregnancy advanced, and give rise to symptoms so severe as to demand immediate surgical relief. A fibroid tumor springing from the lower part of the uterus might so fill the pelvis as to prevent the passage of the child, either prematurely or at term. Subperitoneal or interstitial fibroids that were interfering with pregnancy or promised to interfere seriously with delivery, might be removed by myomectomy. Numerous cases had been reported where this operation had been successfully done without interrupting pregnancy. Only one such case, however, had come under the author's observation. Myomectomy should usually be limited to those cases in which the tumors were not numerous and were easily accessible. In spite of the reported cases of myomectomy, one could not expect the uterus to withstand too much traumatism without rebelling. The part of the uterus from which the tumor sprang was important. Fibroid tumors might be the cause of extrauterine pregnancy. Noble had reported six cases of ectopic pregnancy complicating fibroids. Eight cases were reported by the author to illustrate the various phases of surgical interference during pregnancy.

Vaginal Hysterectomy for Carcinoma of the Cervix. Dr. HENRY T. BYFORD of Chicago said the relative value of the vaginal and abdominal routes was still under discussion. He was satisfied that the permanent results of the

vaginal method might be improved sufficiently to give it an important place in the future, and proposed a method of causing sloughing of the broad ligaments by the combined use of silk ligatures and strong forceps. In this way much more of the connective tissue in the broad ligament and about the cervix could be removed than by either ligatures or forceps, as ordinarily employed. The essential part of the method consisted in ligating the broad and sacro-uterine ligaments as far from the cervix as possible after having pushed the ureters out of the way. After the uterus had been removed, the broad ligaments were pulled still farther down and strong forceps applied still farther away, which were clamped so as to cause sloughing of all tissue within their grasp. Dr. Byford exhibited a pair of forceps which he had devised and which, he thought, obviated some of the objections that were found to the ordinary broad ligament forceps. Most forceps projected too far into the peritoneal cavity, and caused pain; they sometimes failed to grasp the tissues firmly at all points, and thus might not cause prompt and complete sloughing; and they projected too far out of the vulva and were in the way externally. The forceps shown were short, and would not only hold the stump down near or at the vaginal edges, but they did not form a large mass of metal projecting between the thighs. They were blunt and slightly hooked at the end of the blades, and thus not only did not scratch the intestine, but did not allow the pressure to force the edge of the flattened stump beyond their grasp. They were strong enough to exert a uniform pressure that caused sloughing even when left on but a few hours. He usually left them on for twenty-four hours, although ten or twelve would probably be long enough.

Temporary Ventrosuspension of the Uterus.—Dr. Edward H. Ochsner of Chicago, after a brief review of the dangers and disadvantages of permanent ventrofixation and ventrosuspension, gave the technique indications, and end results of a temporary ventrosuspension of the uterus. The operation consisted in passing the needle, armed with a double strand of ten-day unchromicized catgut, through the rectus fascia, rectus muscle, and peritoneum, on the right side, one inch below the lower angle of the peritoneal incision, then through the fundus of the uterus, being careful not to injure the peritoneal covering of the uterus unnecessarily, then cut through the abdominal wall in reverse order to its introduction. This stitch was now tied just tight enough to bring the uterus in contact with the parietal peritoneum, but not tight enough to cause necrosis of the peritoneum. The operation was recommended if, after pelvic operations for inflammatory conditions, the uterus showed a tendency to fall backward after the intra-abdominal work was completed. It was claimed that, if properly applied, it would prevent the uterus from falling backward and becoming adherent to the pelvic floor without making a permanent ventrosuspension or fixation.

Abdominal Aneurysm.—Dr. Murat Willis of Richmond, Va., reported a case of abdominal aneurysm treated by wiring, although the result was unsuccessful. A critical study of 21 cases thus far reported led to the conclusion that surgery so far offered no certain relief for this malady. Of these 21 cases, the subsequent history of three was not recorded; in the remaining 18 death ensued in every case. The duration of life after operation in this series varied from one hour to nine months, with an average duration of less than fifty days. The operative technique, as developed for this condition, would seem to be absolutely perfect, and based upon sound surgical principles, but the fact remained that this method of treatment was disappointing, and the last word had not yet been said concerning the surgical treatment of abdominal aneurysm.

Dr. R. S. Cathcart of Charleston, S. C., reported a case of false aneurysm of the femoral artery following typhoid fever.

Elephantiasis of the Male Genitalia.—Dr. J. Norment Baker of Montgomery, Ala., discussed this subject, and said the comparative rarity of the affection in America furnished the stimulus for preparing a paper on this subject. He reviewed the literature, and reported a very interesting case of elephantiasis in a colored man, aged 52, upon whom he had operated successfully for its removal.

Anatomical and Physiological Restoration Versus Removal of the Internal Generative Organs of Women.—Dr. John E. Cannaday of Charleston, W. Va., said the advantages of waiting and of giving nature a full opportunity in cases of infected fallopian tubes were great. The damage done by inflammation in many cases was small. He spoke of the bearing of the woman's social condition on the case, and pointed out the necessity for the wage-earner of small means to get well quickly. He discussed the desirability of letting his patient decide what was best to be done in many cases. The non-operative treatment of tubal inflammation was really cautious neglect. The measures taken were to divert the attention of the patient. Pelvic massage was of benefit in removing the results of inflammatory attacks. There were numerous valuable methods of treating uterine pathology without the removal of both uterus and disease. It was seldom necessary or advisable to remove the ovaries.

Cancer of the Parotid Gland.—Dr. George A. Hendon of Louisville, Ky., read a paper in which he reported five cases and of having performed an operation successfully in each case.

Extensive Injury to the Abdominal Wall; Operation; Recovery.—Dr. Rufus B. Hall of Cincinnati reported a case of an accident to an infant, seventeen months old, with extensive injury to the abdominal wall, and evisceration of all of the small intestines, with recovery of the patient. The child's mother was giving him a bath by holding him on her lap in the kitchen where she had been canning fruit. To facilitate rinsing off the soap, she stood the child on the drain board of the sink, which was two and a half feet high. The mother left the child standing and went across the room for a towel. The child fell, striking the right side of the abdomen on the top of an empty half-gallon glass Mason fruit jar. The impact broke the jar, telescoping it, leaving four sharp points remaining on the bottom of the can. One of these made a large wound in the side of the abdomen and the intestines at once protruded on to the dirty kitchen floor, picking up several fragments of peelings of tomatoes and pears. The child had lost a great quantity of blood due to the injury of the deep epigastric artery. One prong of the glass cut through the tenth rib, dividing the intercostal artery. Another one made an opening into the abdomen three inches above the large opening. All of the small intestines, the pyloric end of the stomach, and four inches of the ascending colon were outside of the abdomen. There were sticking to the coils of bowel and omentum several pieces of the peelings of pears and tomatoes. When Dr. Hall arrived the child was semiconscious, pulseless, with cold extremities, and rapid, superficial breathing. In addition to the division of the deep epigastric artery and the intercostal artery, there was a ragged wound in the omentum and another in the mesentery. The intestines were largely distended with undigested pears. The temperature twelve hours after the accident was 106.5°, and remained high for twelve hours longer, at which time he succeeded in getting the intestinal tract emptied. Before the bowels were emptied, the child was delirious, with general twitching of the muscles throughout the body. Within two hours after the bowels were emptied, the temperature declined to 100°, and convalescence was established. The child made a good recovery.

Surgical Treatment of Epilepsy.—Dr. W. P. Carr of Washington, D. C., reported twenty operations for

epilepsy, and said that eight of these cases had been cured to date, or were well when last heard from; one after nine years, one eight and a half years, one seven and a half years, one four years, one three and a half years, one after one year, and two after three months. Five of these cases, probably not traumatic, in which the habit was well established, had been cured for over three years; three of them for seven, eight and nine years, respectively. Nearly all the cases were benefited temporarily, most of them being so much improved as to make the operation justifiable. One was confined in the Government Hospital for the Insane, and another, a complete imbecile. Both regained the normal mental condition, and have remained mentally sound to date. Only one patient was not benefited. The best results were in cases apparently most unfavorable. He believed that operation for cases of long standing traumatic epilepsy, and idiopathic or hereditary epilepsy, had been abandoned upon theoretical grounds, without a fair trial of modern surgical methods, and that such cases should be operated upon for the following reasons: (1) There was very strong evidence to show that a considerable proportion of even the most unpromising cases could be cured. (2) In view of the hopeless and progressive nature of the malady, the operation would be justifiable if even a very small percentage could be cured, or even greatly benefited. (3) No systematic attempt had been made to find what percentage of cures might be obtained, since modern methods had made the operation easy and safe, and that such attempts should be made. (4) There was so little danger in the operation of either death or unpleasant sequelæ. (5) Because of the freedom from pain or discomfort of any kind following the operation, which was in marked contrast to the discomfort following most other operations of equal severity.

Successful Operation for Vesicouterine Fistula, with Loss of Function of the Vesical and Urethral Sphincters.—Dr. R. S. Hill of Montgomery, Ala., reported the following case: Patient, 32 years of age, weight 155 pounds, was delivered of her second child in February, 1908, after being in labor eighteen hours, which was more severe and lasted longer than her first confinement, eight years ago. The child was born dead, though fully developed, and presentation was normal. Within one hour after the completion of labor, she felt an intense desire to urinate, which was followed by a tremendous gush of water from the vagina. From this time on the urine passed continually and entirely through the cervix uteri. Vesicouterine fistula was diagnosed. She was brought to the essayist six weeks later, and through a T-shaped incision in front of the cervix uteri the openings into the bladder and uterus, which were about the size of the end of the index finger, were closed with catgut sutures. Union was perfect, but when the patient left the bed it became evident, from the continuation of the urinary incontinence, that the vesical and urethral sphincters had lost their function. She returned home and remained until October 15, when she came back in the same condition, except a three months' pregnancy to complicate matters. The following technique, which so far as the author knew was original, was used: With a metal sound in the urethra as a guide, a median incision was made through the vaginal mucosa from a point one inch on the bladder wall to the meatus urinarius, and then around this orifice. The mucosa was dissected from the underlying structures to the extent of one inch or more transverse measurement. The sound in the urethra was now changed for one of smaller size. Commencing at the bladder end of the denudation, the muscular structure were folded in or brought together with a continuous catgut suture passed transversely, but never deep enough to include the vesical or urethral mucosa. As the gut was made taut after each passage of the needle, the sound was drawn from its grasp. The vaginal mucosa was now trimmed and made to fit snugly over the underlying tissue and held in position with silkworm gut sutures, some of which were carried through the muscular tissues, re-enforcing the catgut sutures. Patient was catheterized with a small soft rubber catheter every four to six hours. The author was opposed to leaving an instrument in the urethra after this operation, and suggested the advisability of establishing vesicovaginal or even suprapubic drainage after the operation, in order not to disturb the parts until firm union was established. The extent of the dissection was to be regulated by the condition found in the individual case. Furthermore, if any one part of the muscular wall, as, for instance, either of the sphincter muscles, appeared more injured than the rest, then a special suture of catgut should be used to repair it.

The following papers were likewise read: "Report of a Case of Urethral Transplantation," by Dr. John D. S. Davis of Birmingham, Ala.; "Operative Treatment of Tuberculous Joints," by Dr. Horace J. Whitacre of Cincinnati, Ohio; "The Transverse Abdominal Incision," by Dr. S. M. D. Clark of New Orleans, La.; "Further Observations on Transfusion, with a Note on Hemolysis," by Dr. George W. Crile of Cleveland, Ohio.

Officers.—*President*, Dr. Stuart McGuire, Richmond, Va.; *First Vice-President*, Dr. John Young Brown, St. Louis, Mo.; *Second Vice-President*, Dr. R. S. Cathcart, Charleston, S. C.; *Treasurer*, Dr. Wm. S. Goldsmith, Atlanta, Ga.; *Secretary*, Dr. William D. Haggard, Nashville, Tenn.

Hot Springs, Va., was selected as the place for holding the next annual meeting; time, third Tuesday in December, 1909.

Philadelphia Neurological Society.

At a stated meeting, held December 18, Dr. A. A. Eshner exhibited "A Case of Hematomyelia." The patient was a woman 25 years old, who was suddenly seized with numbness and loss of power in the lower extremities, followed by loss of control of the sphincters and loss of temperature-sense, and of painful sensibility in the lower half of the body, so that she had been burned without being sensibly conscious of the accident. While tactile sensibility was preserved generally, in the right lower extremity the patient was unable to recognize the character of the touching object. The knee-jerks were exaggerated and the Babinski reflex was present, with abortive ankle-clonus on the left. Girdle-sense also was present. Dr. Eshner also described "A Case of Syringomyelia." The patient was a woman, 27 years old, who presented loss of all forms of sensibility in the right upper extremity, and impairment of thermal and painful sensibility in the left upper extremity, together with exaggerated knee-jerks and Babinski reflex. Dr. John K. Mitchell presented "A Case of Progressive Muscular Atrophy, with Remarkable Improvement." The patient was a man, 25 years old, who, following an attack of scarlet fever, exhibited progressive muscular wasting and weakness over the entire body, without sensory disturbances or involvement of sphincters. Under treatment with rest, massage, electricity, and feeding the man gained some 20 pounds in weight and became able to walk long distances, whereas previously he had been scarcely able to get about. The possibility of multiple neuritis and of progressive muscular dystrophy was considered. Dr. Charles K. Mills exhibited "A Case Showing Hypostereognosis and Impairment of Sensibility, Exaggerated Reflexes, Including the Babinski Phenomenon, and a Peculiar Mental State." The patient was a man, about 35 years old, without syphilitic history, who was suddenly seized with vertigo, and who developed

the symptoms mentioned, together with a peculiar happy and contented state of mind, without evident delusions. There were no ocular changes and no derangement of the sphincters. The possibility of multiple sclerosis, of paretic dementia, and of hysteria was considered. Dr. F. X. Dercum exhibited "Two Cases of Astasia Abasia." One occurred in a girl, about 17 years old, in whom the condition had been present from early childhood, following an acute infectious disease. When she first came under observation she was scarcely able to walk and to stand, but under training and suggestion she was acquiring skill in both directions. The second case occurred in a woman, about 35 years old, who in walking placed the left foot slightly forward and then brought the right foot after, and permitting the body to descend with flexion of the right thigh on the leg. The same movements were gone through with every step that was taken. Dr. Dercum also presented a communication entitled "Association and Reinforcement in Aphasia." He pointed out that under certain conditions aphesics became capable of uttering words that ordinarily they appeared unable to articulate. Such reinforcement might be effected through any of the special senses or even under psychic stimulation. Dr. S. D. Iggham read a paper entitled "Encephalitis, with a Report of Two Cases with Necropsy." Drs. T. H. Weisenburg and W. F. Guilfoyle presented a communication entitled "Tumors of the Lateral and Third Ventricles." They reported two illustrative cases, in both of which there was loss of upward associated movement of the eyeballs and anatomical involvement of the posterior longitudinal bundle, and it was suggested that there might be some pathological connection between the two facts.

Idiopathic Enlargement of the Esophagus.—Dr. Armin Huber of Zurich has published a very detailed account of two cases of idiopathic enlargement of the esophagus, an affection which is rarely diagnosed during the patient's life. Dr. F. Krauss wrote an elaborate monograph on this condition some years ago, and Dr. Neumann in 1900 reported 70 cases, most of which, however, were discovered by the pathologist only. The improvement of skiagraphy during recent years has made this condition easier to diagnose. As regards etiology Dr. Krauss attributes the origin of the disease to a primary nervous lesion—namely, partial paresis of the vagus nerve and consequent atony of the longitudinal muscles of the esophagus combined often with local contraction of the transverse muscles. In several cases some infectious disease such as diphtheria was responsible for the malady. In Dr. Huber's two cases the patients were aged 52 years and 20 years respectively; the important points were (1) the establishment of an exact diagnosis during life by means of skiagraphy; and (2) the relief afforded to the patients by artificial feeding through an esophageal tube.—*The Lancet.*

Temporosphenoidal Abscess Rupturing into the Lateral Ventricle.—A. A. Gray recently reported to the Glasgow Medico-Chirurgical Society a case of this nature. On the opening of the abscess, very fetid pus mixed with cerebrospinal fluid escaped. After operation great improvement took place. Consciousness and intelligence were quite restored, and the various paralyses, previously present, disappeared to a great extent. A few days afterward, however, meningitis set in, and the patient died fourteen days after operation. Post-mortem examination revealed a long and tortuous sinus passing almost horizontally backward from the abscess and opening into the lateral ventricle at the point where the posterior joins the middle cornu. The infection thus had reached the right lateral ventricle, and had then extended to the third ventricle, from there to the left lateral ventricle and downward to the fourth ventricle, through the aqueduct of Sylvius. From the fourth ventricle pus had escaped into the arachnoid space, and caused a basal meningitis, and involved all the cranial nerves. The chief interest of the case lay in the comparatively long time the patient lived after the rupture of the abscess into the lateral ventricle. This was probably due to the operation being performed very soon after the rupture, and from the rupture being more a gradual leakage into the ventricle rather than a sudden burst.—*British Medical Journal.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

New Hampshire State Board of Medical Examiners.

Concord, July 15 and 16, 1908.

ANATOMY.

1. Name all the muscles that have to do with respiration.
2. Locate, anatomically, the normal heart.
3. Name and give distribution of third pair of cranial nerves.
4. What are the organs of assimilation? Name them.
5. What is meant by the vasomotor nervous system?
6. Place and describe the nasal bone.
7. Describe the hip joint.
8. Describe the pectoral muscles.
9. Give origin, course and termination of the popliteal artery.
10. Describe the uterus and its appendages.

PHYSIOLOGY AND HYGIENE.

1. Define albuminoids. Mention two, and where found.
2. What is epithelial tissue? Give its general function.
3. Describe visceral muscle. What is its physiologic property?
4. What are the physiological properties of nerves?
5. What are the forces concerned in the circulation of the blood?
6. What are the functions of the medulla oblongata and pons?
7. What are the best methods of food preservation?
8. What substances are found normally in water?
9. What are the more common methods of sewage disposal? Which will you advise for large cities?
10. Discuss (in brief) the hygiene of occupation.

CHEMISTRY.

1. Define anesthetics, sedatives, narcotics. Give an example of each.
2. Name an antidote to carbolic acid. How would you diagnose carbolic acid poisoning before death?
3. Complete the following formulæ:
   $2HCl + CaCO_3 = ?$
   $Zn + H_2SO_4 = ?$
   $Ba + 2\ HCl = ?$
4. What are isomeric compounds?
5. Give symptoms and treatment for chronic lead poisoning.
6. Give treatment for phosphorus poisoning.
7. Describe properties of hydrogen. How prove that it is not a supporter of combustion?
8. Give formulæ for (*a*) sulphuric acid; (*b*) nitric acid; (*c*) carbolic acid.
9. What is the difference between analysis and synthesis?
10. How is oxalic acid obtained, and what are its antidotes?

MATERIA MEDICA, THERAPEUTICS AND THE PRACTICE OF MEDICINE.

1. Mention the silver salts used in medicine and give the dose of each.
2. Give the materia medica of gelsemium and its therapeutic indications.
3. Give the materia medica and therapeutic uses of ergot.
4. Differentiate chronic eczema from psoriasis.
5. What is hematemesis? Mention the most reliable remedy for its relief.
6. Give clinical description of tubercular meningitis. Is it usually primary, and at what age is it most common?
7. What is tetanus? Give incubative period of acute tetanus and differentiate from strychnine poisoning.
8. What is acute poliomyelitis anterior? Give clinical description.
9. Give etiology and treatment of hemothorax.
10. What treatment would you recommend for post diphtheritic paralysis? What is the prognosis?

PATHOLOGY AND DIAGNOSIS.

1. Give pathology and diagnosis of pyonephrosis.
2. Differentiate between actinomycosis and tubercular infection of tissues of neck.
3. What symptoms during first year of life would lead you to make a diagnosis of congenital pyloric stenosis?
4. Give pathology and diagnosis of herpes zoster.

5. Give pathology and diagnosis of articular rheumatism.
6. Give pathology and diagnosis of typhoid fever.
7. Give pathology and differential diagnosis between smallpox and chickenpox.
8. Describe the postmortem appearance of a case of intussusception.
9. Describe a case of bronchopneumonia.
10. Describe the symptoms of disease of the suprarenal capsule.

OBSTETRICS.

1. At what time of gestation is the placenta formed?
2. Give symptoms and diagnosis of ectopic gestation.
3. Give the common causes of sub-involution of the uterus.
4. Give treatment for specific vaginitis; name its most common sequelæ.
5. Under what circumstances would you irrigate after confinement, and with what solutions?
6. Describe the placental circulation.
7. How would you manage a case of prolapsed funis?
8. Give best method of management of shoulder presentation.
9. What is the difference between presentation and position?
10. Define metrorrhagia; what would you suspect should it occur subsequent to the menopause?

SURGERY.

1. Differentiate between acute and chronic perforation of gastric ulcer, and give treatment of each.
2. Describe technique of suprapubic drainage of bladder.
3. Give symptoms of adenoids and describe operation for removal.
4. Describe the effects of ether and chloroform on the respiratory and cardiac centers.
5. Differentiate between inguinal and femoral hernia, and give treatment of each.
6. Enumerate causes of vomiting which may require surgical interference.
7. Give diagnosis and treatment of iritis.
8. Name the various dislocations of the shoulder joint and give symptoms of each.
9. Give diagnosis of mastoid disease.
10. Describe briefly inflammation, cellulitis, suppuration, and gangrene.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NEW HAMPSHIRE STATE BOARD OF MEDICAL EXAMINERS.

Concord, July 15 and 16, 1908.

PHYSIOLOGY AND HYGIENE.

1. *Albuminoids* are "a miscellaneous collection of those proteins which are neither albumins nor proteids. About the only character which they have in common is that they are insoluble in the neutral solvent of the albumins and proteids. They can be dissolved only after undergoing chemical change. They are found in connective tissues, cartilage, bone, epidermic tissues, etc."—(Witthaus' *Essentials of Chemistry.*)

Two albuminoids: Elastin, found in elastic connective tissue; and *keratin,* found in the surface layer of the skin, hair, and nails.

2. *Epithelial tissue* consists of one or more layers of nucleated cells, united by an interstitial cement substance, resting on a basement-membrane; it covers all the surfaces of the body.

Its *function* is: (1) Protection, (2) secretion, (3) motion (ciliary), (4) special sensation, (5) absorption.

3. *Visceral muscle* is made up of nucleated spindle-shaped cells, which are fastened into bundles by a cement substance. It is not under the control of the will, and is characterized, physiologically, by its tendency to *rhythmical movement,* and to *peristalsis.*

4. *The physiological properties of nerves,* are: (1) Irritability, (2) conductivity of nerve impulses, (3) electrotonus, (4) incapability of fatigue.

5. *The forces concerned in the circulation of the blood,* are: The force and frequency of the contractions of the heart, the elasticity and tone of the arterial walls, the resistance in the capillaries and tissues, the values in the veins, the contraction of the muscles, the aspiration of the thorax.

6. *The functions of the medulla oblongata and pons,* are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of co-ordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions: Respiration, salivary secretion, mastication, sucking, vomiting, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

7. *Methods of food preservation,* are: Drying, salting, freezing, refrigeration, smoking, air-exclusion, sterilization, and the use of antiseptics and preservatives (such as borax, boric acid, salicylic acid, formaldehyde, acetic acid, sulphurous acid, alum, salt, and sugar). Which is the *best* method, depends upon the kind of food to be preserved; but the addition of strong preservatives and antiseptics should be avoided, if air-exclusion and refrigeration, etc., are available.

8. *What is normally found in water,* depends upon the source of the water. Chemically pure water contains no solids; and it consists of hydrogen and oxygen chemically combined in the proportion of two atoms of the former to one of the latter element. Rain water, as it descends through the air, takes up nitrogen, oxygen, and carbon dioxide, also a little ammonia, and some suspended matters. The water can then become contaminated in various ways, and it may contain almost any contamination from perfectly harmless matters up to sewage and pathogenic microorganisms.

CHEMISTRY.

1. *Anesthetics* are agents which either (1) produce loss of sensibility of the tissues over a limited area, as cocaine; or (2) produce unconsciousness as well as abolition of sensation, as chloroform.

Sedatives are agents which allay excitement and functional activity, and sometimes tend to diminish pain; as potassium bromide.

Narcotics are agents which produce sleep or stupor, and allay pain; as opium.

2. The chemical antidotes to carbolic acid are (1) alcohol, or (2) the soluble sulphates, such as magnesium or sodium sulphate. With the carbolic acid these salts form insoluble sulphocarbolates. Before death carbolic acid poisoning can be diagnosed by the hoarseness of the voice, in addition to all the other signs of corrosion, such as eschars on mucous membrane of mouth, vomiting, purging, abdominal pain, cold perspiration, pinched and anxious face, collapse, etc. The urine may become dark.

3. $2HCl + CaCO_3 = CaCl_2 + H_2O + CO_2$
$Zn + H_2SO_4 = ZnSO_4 + H_2$
$Ba + 2HCl = BaCl_2 + H_2$

4. *Isomeric compounds* are substances which, while differing in properties, possess the same percentage composition.

5. The *symptoms* of chronic lead poisoning are: Wrist drop, severe colic around the umbilicus, constipation, feces clay colored, blue line on the gums at the junction with the teeth.

The *treatment* is first to remove the cause; then administer a purge of jalap and calomel combined with opium; iodide of potassium should also be given to help in the elimination of the lead.

6. The treatment of phosphorus poisoning is to administer first an emetic, then old French oil of turpentine, or solution of potassium permanganate, and avoid giving any oils or fat with the food.

7. HYDROGEN is a colorless, odorless, tasteless gas, the lightest known substance; it has a great affinity for oxygen; it supports neither combustion nor respiration; it is a necessary constituent of all acids; the gas will burn with a pale blue flame, giving little light, but an intense heat. Its atomic weight is 1; its molecular weight is 2; and it is univalent.

To prove that hydrogen is not a supporter of combustion: Introduce a lighted taper into a vessel of hydrogen; the taper will be extinguished, but the hydrogen itself will burn at the mouth of the vessel.

8. The formula for (*a*) sulphuric acid is H_2SO_4; (*b*) nitric acid, HNO_3; (*c*) carbolic acid, C_6H_5OH.

9. *Analysis* is the splitting up of a compound into its elements or into simpler compounds.

Synthesis is the building up of a compound from elements or from simpler compounds.

10. *Oxalic acid* is obtained by the oxidation of starch, sugar, wood, or other organic matter, by nitric acid or potassium hydroxide.

Antidotes: Magnesia or slaked lime; or calcium carbonate; the stomach should then be washed out, first with lime water, then with water.

MATERIA MEDICA, THERAPEUTICS AND THE PRACTICE OF MEDICINE.

1. *Silver salts, with doses:* Silver nitrate, gr. 1/5; silver oxide, gr. j; silver cyanide, gr. 1/30; unofficial salts, are: Silver iodide, gr. 1/2; argyrol, gr. vij.

2. GELSEMIUM is the yellow jasmine; its chief constituents are gelsemine, gelseminine, and gelseminic acid. *Dose,* gr. j.

Preparations: Fluid extract of gelsemium, ℥j; tincture of gelsemium, ℥viij.

Action: "When given internally gelsemium acts as a powerful depressant to the respiratory circulatory, and nervous systems. It acts as a depressant to the heart muscle and vagus nerves, and under its influence there is a diminution in the pulse force and blood pressure. It primarily depresses the sensory side of the spinal cord; but later, if given in large amount, depresses the motor side. The drug has no effect upon the spinal nerves, but the motor cranial nerves are paralyzed by large doses. In moderate amounts it causes the respiration to become slow and feeble, and in lethal quantities paralyzes the respiratory centers."—(*U. S. Dispensatory.*)

Therapeutic indications: Headache, migraine, asthma, whooping cough, nervous cough, spasmodic dysmenorrhea, torticollis, and other conditions depending upon localized muscular spasm.

3. ERGOT. *Derivation:* The selerotium of the claviceps purpurea.

The *composition* of ergot is indefinite; the chief constituents are: Ergotine, ergotinine, ecboline, sphacelic acid, ergotinic acid, cornutine, tannic acid, and other substances. Most of these ingredients contract the blood-vessels; the cornutine, in addition, is credited with the chief part in contracting the uterus.

The *official preparations* with doses are: Ergot, thirty grains; extract of ergot, seven and a half grains; fluid extract of ergot, thirty minims; wine of ergot, two drams.

Physiological action: Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vaso-constrictor, hemostatic, and oxytocic. It is also a cardiac sedative, it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

Indications for the therapeutic application: To promote uterine contractions during third stage of labor; fibroids, menorrhagia, post-partum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

4.

ECZEMA.	PSORIASIS.
1. Polymorphous in character.	1. Uniform in character.
2. Generally found on the flexor surfaces.	2. Generally found on the extensor surfaces.
3. The patches are not sharply defined, but gradually merge into the surrounding healthy skin.	3. The patches are sharply defined.
4. Decided serous exudation.	4. Dry scales.
5. Marked itching and burning.	5. No marked itching and burning.
6. Healing begins at the periphery.	6. Healing begins in the center.

5. *Hematemesis* is the vomiting of blood. *Reliable remedies for its relief,* are: morphine, adrenalin, ergot, and ice.

6. *Tubercular meningitis* is not generally primary. It is most common in early childhood, say from two to six years of age.

7. *Tetanus* is an acute infectious disease due to the tetanus bacillus. The *period of incubation* is from three or four to twenty days.

Differential diagnosis: In *tetanus,* the onset is gradual, is apt to begin with trismus, swallowing is difficult or impossible, the condition is persistent, consciousness is dulled or lost, and there is history of a wound or injury.

In strychnine poisoning, the onset is more sudden, the muscles of the jaw and neck are generally the last to be affected, there are marked remissions with muscular relaxation, consciousness is retained, and there is no history of a wound or injury.

10. *Treatment of postdiphtheritic paralysis* consists of: Liquid but nourishing diet, careful hygiene, strychnine, iron, quinine, massage, and the electric current.

Prognosis is, as a rule, good; except when the heart or respiratory muscles are involved.

PATHOLOGY AND DIAGNOSIS.

2. *In actinomycosis:* The skin is livid, soft in the center of the swelling, and brawny at its periphery, tends to break down, and the fluid or semifluid contents show the actinomyces or "ray fungus." The lymphatics are not as a rule involved.

In tubercular infection: There is a slow growing, circumscribed, painless, and fluctuating swelling; the tubercle bacillus may be found; and the lymphatics are involved, and eventually show abscess formation.

3. The symptoms during the first year of life that would lead one to make a diagnosis of congenital pyloric stenosis, are: Persistent, and apparently causeless vomiting; constipation, and inanition. There *may be* slight gastric dilatation, and palpation *may* show a swelling at the pylorus.

8. "In the postmostem examination, in a case of death from intussusception, the condition is very characteristic. Peritonitis may be present or an acute infection of the serous membrane. When death occurs early, as it may do from shock, there is little to be seen. The portion of bowel affected is large and thick, and forms an elongated tumor with a curved outline. The parts are swollen and congested, owing to the constriction of the mesentery between the layers. The entire mass may be of a deep livid red color. In very recent processes there is only congestion, and perhaps a thin layer of lymph, and the intussusception can be reduced; but when it has lasted for a few days, lymph is thrown out, the layers are glued together, and the entering portion of the gut cannot be withdrawn." (Osler.)

10. *The symptoms of disease of the suprarenal capsules* are: (1) General weakness, both muscular and cardiovascular; headache, vertigo, syncope, or convulsions may occur. (2) The skin is pigmented, generally bronze. (3) Nausea, vomiting, anorexia, or other gastrointestinal symptoms may be present. (4) Pain in the region of the suprarenals, and also anemia have been noticed, but they may be absent.

OBSTETRICS.

1. "The placenta is formed by the union of the chorion frondosum and the decidua serotina, and therefore is composed of fetal and maternal tissues. In the third or fourth month of pregnancy it constitutes a distinct structure, although its site is indicated at a much earlier period by the increased thickness of the chorion at that point." (Williams' *Obstetrics.*)

2. "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility. Nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy. Pains are often very severe, with marked tenderness within the pelvis. Such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating. This tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*" (*American Text-Book of Obstetrics.*)

3. *Common causes of subinvolution of the uterus* are: Lacerations of the cervix; absorption of septic products; mismanagement of the convalescent stage of the puerperium, chiefly too early rising; tedious labors; misplacement of the uterus; retained clots or membranes; tumors of the uterus.

4. SPECIFIC VAGINITIS. *Treatment:* Rest in bed, salines, mild unirritating diet, bathing of external genitals, copious vaginal douches of bichloride of mercury 1:2000 three or four times a day; later, the vagina may be swabbed daily with a solution of nitrate of silver 1 to 5 per cent., or with a solution of potassium permanganate 1 per cent.

Sequelæ: Vulvovaginal abscess, endometritis, salpingitis, ovaritis, peritonitis, sterility.

5. *Irrigation after confinement* is done: (1) By some practitioners, as routine treatment after every labor; (2) by others only when there have been repeated vaginal examinations, or (3) in case of foul lochia; (4) or after some operative procedure; (5) in case of sepsis. *Intrauterine douche* is indicated when the hand or instruments have been introduced into the uterus, or when sepsis is suspected. The solutions for *vaginal douche* may be: Hot 1 per cent. creolin mixture in boiled water; or bichloride of mercury 1:10000 to 1:5000; or decinormal salt solution.

For *intrauterine douche:* Plain sterile water, decinormal salt solution, creolin 1-2 per cent., a bichloride of mercury 1:10000 followed by plain sterile water.

7. *Treatment of prolapsed funis* consists in: (1) Not rupturing the membranes prematurely, unless there is some positive indication; (2) postural treatment, in which the woman is placed on her back or on the opposite side to that on which the cord lies, with hips and pelvis elevated, or the knee-chest position may be adopted; (3) reposition of the cord, either manually, or with some form of repositor; (4) speedy delivery, by forceps or podalic version.

8. In cases of *shoulder presentation,* if seen before labor, version should be performed to correct the malpresentation; in case of impaction a Cesarean section is indicated; sometimes decapitation or embryotomy has been performed, but a Cesarean section is preferable. Cases of shoulder presentation have been known to terminate spontaneously, but it is not advisable to rely on this possibility.

9. By *presentation* is meant the part of the fetus which presents at the pelvic brim; examples—vertex, breech, face.

By *position* is meant the relation between a point on the fetus and a point on the maternal pelvis; examples—in a vertex presentation the position may be (1) left occipito-anterior, (2) right occipito-posterior, (3) right occipito-anterior, (4) left occipito-posterior.

SURGERY.

1. According to Robson and Moynihan, in *acute perforation:* The ulcer gives way suddenly and completely; a larger or smaller hole results, and through this the stomach contents are free to escape at once into the general cavity of the peritoneum. There may be no premonitary symptoms. Pain of a sudden, sharp, stabbing character, intolerable and spreading from epigastrium over whole abdomen; collapse, a drawn face, anxious expression, a pale cold clammy skin, livid lips, blanched face, hurried and shallow respirations, thin and rapid pulse, vomiting, intense thirst, scanty or suppressed urine, abdomen at first retracted, but later bulging—may all be present. It is more common on the anterior surface.

In chronic perforation: The ulcer has slowly eaten its way through the stomach wall, and a protective peritonitis has had time to develop at the base. The escape of stomach contents is therefore only local; barriers of lymph confine the fluid to a restrictive area, and a perigastric abscess may form. It occurs more frequently on the posterior surface of the stomach, and the perigastric abscess occasioned thereby is recognized as "subphrenic."

3. *Symptoms of adenoids:* Mouth-breathing; snoring; open mouth; a vacant, dull expression of the face; modification of the voice (nasal twang), with inability to pronounce certain letters.

Effects: Earache and other ear affections; mental deficiency; frequent attacks of coryza; nose-bleed; stunted growth; convulsions, laryngismus stridulus, and various other neuroses may also be noticed.

5. *In inguinal hernia:* The impulse is felt above Poupart's ligament; the inguinal canal may be filled; the hernia emerges on the inner side of the pubic spine (above the inner end of Poupart's ligament); and is apt to recur readily after reduction.

In femoral hernia: The impulse is felt below Poupart's ligament; the inguinal canal is empty; the hernia emerges on the outer side of the pubic spine, and does not recur so readily after reduction.

For *inguinal hernia,* Bassini's or Halsted's operation should be performed; for *femoral* hernia, Bassini's operation.

6. *Causes of vomiting which may require surgical interference:* Appendicitis, cancer or ulcer of the stomach, perforating ulcer of the duodenum, gallstone colic, intestinal obstruction, or strangulation, or intussusception, cerebral tumors, hernia.

7. *Iritis is diagnosed* by: (1) The altered appearance of the iris; it may be swollen, dull, lusterless, or changed in color. (2) The pupil is contracted, grayish, sluggish in action, and irregular. (3) The contents of the aqueous chamber may be turbid, or may contain pus, fibrin, or blood. (4) There are present pain, photophobia, lacrymation, and interference with vision.

Treatment consists in: Atropine, dionine, the application of leeches to the temples, hot fomentations, absolute rest in bed, protection from the light, light diet, purgatives, abstinence from alcohol, avoidance of all use of the eyes for near work, constitutional treatment varying according to the etiology, paracentesis, and iridectomy.—(From May's *Diseases of the Eye.*)

8. The *various dislocations of the shoulder-joint* are: (1) Subcoracoid—forward, inward, and downward. (2) Subglenoid—downward, forward, and inward. (3) Subspinous—backward, inward, and downward. (4) Subclavicular—forward, inward, and upward.

The *special diagnostic signs* are: (1) *Subcoracoid:* The head of the humerus is felt below the outer end of the clavicle; there is little or no shortening of the limb; the elbow is directed outward and backward.

(2) *Subglenoid:* The head of the humerus can be felt in the axilla; the arm is decidedly lengthened; the elbow is flexed; and there are signs of pressure on vessels and nerves.

(3) *Subspinous:* The head of the humerus is felt below the acromion process and behind; the arm is rotated inward, and the elbow is displaced outward.

(4) *Subclavicular:* The head of the humerus is felt below the clavicle; the elbow is far from the side; and the limb may be shortened.

9. Mastoid disease is characterized by: Rise of temperature (up to 103° F.), tenderness, and pain over the mastoid process, which may be remittent or persistent; redness and swelling over the mastoid; bulging of the posterior and superior wall of the auditory canal; if the periosteum is affected, the auricle is unusually prominent; there may be fluctuation if pus is present.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	
Arizona*	Ancil Martin, Phoenix	Phoenix	April 5
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April 6
Colorado	S. Van Meter, 1723 Tremont Street, Denver	Denver	April 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	March 9
Delaware	J. H. Wilson, Dover	Dover	June 15
Dist of Col'bia.	Geo. C. Ober, Washington	Washington	April 13
Florida*	J. D. Fernandez, Jacksonville	Tallahassee	May 19
Georgia	E. R. Anthony, Griffin	Atlanta	May —
Idaho	W. F. Edward, Pocatello	Boise	April 6
Illinois	J. A. Egan, Springfield	Chicago	Jan. 18
Indiana	W. T. Gott, Indianapolis	Indianapolis	May 25
Iowa	Louis A. Thomas, Des Moines	Des Moines	
Kansas	D. P. Cook, Clay Center	Kansas City	Feb. 9
Kentucky*	J. N. McCormick, Bowling Green	Louisville	April 27
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May 20
Maine	Wm. J. Maybury, Saco	Portland	March 9
Maryland	J. McP. Scott, Hagerstown	Baltimore	June 15
Massachusetts*	E. B. Harvey, State House, Boston	Boston	March 9
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 8
Minnesota	W. S. Hall, St. Paul	St. Paul	April 6
Mississippi	S. H. McLean, Jackson	Jackson	May 11
Missouri	J. A. B. Adcock, Warrensburg	Kansas City	May 4

Wisconsin	J. V. Stevens, Jefferson	Milwaukee	
Wyoming	S. B. Miller, Laramie	Cheyenne	Feb. 10

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PORZELLANFÜLLUNGEN UND DEREN IMITATIONEN. Von Zahnarzt Dr. CURT FRITZSCHE. 8vo, 58 pages; paper; illustrated: 2 marks. Verlag von Julius Springer, Berlin, Germany.

A MANUAL OF BACTERIOLOGY. By R. TANNER HEWLETT, M.D., F.R.C.P., D.P.H. (Lond.). 8vo, 638 pages; cloth; illustrated; $4.20 net. P. Blakiston's Son & Co., Philadelphia, Pa.

THERAPEUTICS OF THE CIRCULATION. By LAUDER BRUNTON, M.D., D.Sc., LL.D. (Edin.), LL.D. (Aberd.), F.R.C.P., F.R.S. 8vo, 280 pages; cloth; illustrated; $1.50. P. Blakiston's Son & Co., Philadelphia, Pa.

APPLIED PHYSIOLOGY FOR MEDICAL STUDENTS. By ROBT. HUTCHINSON, M.D., F.R.C.P. 298 pages; cloth; 12mo; illustrated. Longmans Green & Co., New York, N. Y.

SUGGESTIVE THERAPEUTICS, APPLIED HYPNOTISM, PSYCHIC SCIENCE. By HENRY S. MUNRO, M.D. 8vo, 300 pages; cloth. C. V. Mosby Co., St. Louis, Mo.

ARTERIOSCLEROSIS. By LOUIS M. WARFIELD, A.B., M.D. 12mo, 165 pages; cloth; illustrated. C. V. Mosby Co., St. Louis, Mo.

PRACTICAL POINTS IN ANESTHESIA. By FREDERICK-EMIL NEEF, M.D. 16mo, 46 pages; cloth; 60 cents. Surgery Pub. Co., New York, N. Y.

DIE SPRACHE DES KINDES UND IHRE STÖRUNGEN. Von Dr. PAUL MAAS. 8vo, 125 pages; paper, M. 2.80; cloth, M. 3.50. Curt Kabitzsch (A. Stubers Verlag), Würzburg, Germany.

GONORRHEA IN WOMEN. By PALMER FINDLEY, M.D. 4to, 112 pages; cloth. C. V. Mosby Co., St. Louis, Mo.

DIGESTION ET NUTRITION, APERÇUS DE MÉDECINE PRATIQUE. Par le Dr. E. MONIN. 16mo, 376 pages; paper; 4 francs. Vigot Frères, Éditeurs, Paris, France.

LES COLLOÏDES EN BIOLOGIE ET EN THÉRAPEUTIQUE, LE MERCURE COLLOÏDAL ÉLECTRIQUE. Par G. STODEL. 8vo, 282 pages; paper; 6 francs. Vigot Frères, Éditeurs, Paris, France.

INDICATIONS OPERATOIRES DANS LES AFFECTIONS DE L'ESTOMAC. Dr. A. DELANGRE. 8vo, 188 pages; paper; 5 francs. Vigot Frères, Éditeurs, Paris, France.

LEITFADEN DER HYGIENE FÜR STUDIERENDE, ÄRZTE, ARCHITEKEN, INGENIEURE UND VERWALTUNGSBEAMTE. Von Dr. AUG. GÄRTNER. 4to, 634 pages; paper; illustrated; Brosch, M. 7.60; Geb., M. 8.60. Verlag von S. Karger, Berlin, Germany.

ACTION DE LA CONTRACTION UTÉRINE SUR L'OEUF HUMAIN. Dr. PAUL BOUQUET. 4to, 175 pages; paper; illustrated. G. Steinheil, Editeur, Paris.

TASCHENBUCH DER THERAPIE. Von Dr. M. T. SCHNIRER. 32mo, 394 pages; cloth; 2 marks. Curt Kabitzsch (A. Stubers Verlag), Würzburg, Germany.

APPLIED SURGICAL ANATOMY. By GEORGE WOOLSEY, A.B., M.D. 8vo, 601 pages; cloth; illustrated. Lea & Febiger, Philadelphia.

PHYSICAL DIAGNOSIS. JOHN C. DA COSTA, JR., M.D. 8vo, 548 pages; cloth; illustrated. W. B. Saunders Co., Philadelphia.

SYPHILIS UND NERVENSYSTEM. Von Dr. MAX NONNE. 4to, 669 pages; paper; illustrated. Verlag von S. Karger, Berlin, Germany.

DIE PLACENTA MARGINATA UND IHRE ENTSTEHUNG. Von Dr. P. SFAMENI. 4to, 70 pages; paper. Verlag von S. Karger, Berlin, Germany.

DIE PALPABLEN GEBILDE DES NORMALEN MENSCHLICHEN KÖRPERS UND DEREN METHODISCHE PALPATION. Von Dr. TOBY COHN. 4to, 376 pages; paper; illustrated. Verlag von S. Karger, Berlin, Germany.

DIE LEHRE VON DER KONGENITULEN TUBERKULOSE MIT BESONDERER BERÜCKSICHTIGUNG DER PLACENTARTUBERKULOSE. Von Dr. ANTON SITZENFREY. 8vo, 156 pages; paper; illustrated. Verlag von S. Karger, Berlin, Germany.

DIE KOMPLIKATIONEN DER STIRNHOHLENENTZÜNDUNGEN. Von Dr. P. H. GERBER. 4to, 457 pages; paper; illustrated. Verlag von S. Karger, Berlin, Germany.

ANATOMIE UND MECHANISMUS DER SKOLIOSE. Von weil Dr. CARL NICOLADONI. 8vo, 58 pages; illustrated. Urban & Schwarzenberg, Berlin-Wein, Germany.

PHYSICIANS' VISITING LIST. 16mo; leather. Blakiston's Son & Co., Philadelphia, Pa.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 9, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	507	162
Diphtheria	394	42
Measles	538	12
Scarlet Fever	305	15
Smallpox	—	—
Varicella	206	—
Typhoid Fever	46	6
Whooping Cough	30	5
Cerebrospinal Meningitis	8	8
Malarial Fever	—	—
Totals...	2034	250

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, for the week ending January 8, 1909:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Arkansas, Little Rock	Dec. 15–Jan. 2	23	..
Indiana, La Fayette	Feb. 21–28	7	..
Kansas, Wichita	Dec. 19–26	1	..
Maine, General:			
Canadian Border	Dec. 19–26	..	Present
St. Agatha	Dec. 29	15	..
Van Buren	Dec. 29	2	..
Nebraska, South Omaha	Dec. 19–26	1	..
Pennsylvania, New Kingstown	Dec. 29	..	Present

THE COMMON AND UNCOMMON LOCALIZATION OF OTITIC BRAIN ABSCESS, AS ILLUSTRATED BY TWO CASES, WITH RECOVERY.*

By B. SACHS, M.D.,

AND

A. A. BERG, M.D.,

NEW YORK.

Of all brain lesions calling for operative interference, brain abscess, and particularly otitic brain abscess, has proved to be the most promising. So large a number of successful cases have now been reported that we must regard the condition as one which, if diagnosticated promptly and correctly, will yield satisfactory results. It is all the more important that we should recognize the difficulties which in some instances preclude the possibility of complete recovery, so that we may some day consider the prognosis of surgical intervention in cerebral abscess as favorable, as in many abscesses located within the abdominal cavity.

The difficulties which we wish to consider in this brief communication are, first, those of localization; and secondly, those of the surgical treatment of brain abscess with special reference to the question of drainage. As to localization, abscess following upon otitic and mastoid disease is situated commonly in the temporo sphenoidal lobes or in the cerebellum. It is far less common in other parts of the brain. Ordinarily, the abscess is developed in immediate proximity to the inflamed and infected area; but if the abscess be located in the motor areas, or in other distant parts of the brain, it can only be due to infection carried from the site of inflammation to a distant point. If the abscess is situated in the temporosphenoidal lobe of the left side there will be, in addition to the general symptoms (such as headache, somnolence, nausea, vomiting, slight optic neuritis) slight hemiparesis and the symptoms of impairment of speech perception. While the patient may be able to articulate and to use language spontaneously, the perception and interpretation of speech may be more or less defective. Sensory aphasia is no doubt a very common accompaniment of otitic brain abscess situated in the temporosphenoidal lobe, more particularly if such abscess be in the left half of the brain. It is a symptom which is not always apparent unless specially examined for. It is present so regularly in temporosphenoidal abscesses following upon mastoid disease of the left side, that it is a little puzzling to know why it is so rarely reported. While the statistics may show that temporosphenoidal abscess in the right half is a little more common than abscess in the left, the difference is not so great as alone to account for the neglect of this symptom. There has been some dispute of late as to the exact character of speech disturbance in accordance with a lesion in the third frontal convolution or in the temporosphenoidal area, but all neurologists will agree that in lesion of the left temporosphenoidal lobe there must be at least some speech disturbance, and from personal experience, and for all practical purposes, it will be wise to adhere to the older distinctions between motor and sensory aphasia, and to claim that in these cases of temporosphenoidal abscess in the left half of the brain, the symptoms of sensory aphasia will be present. Right temporosphenoidal abscess is sometimes associated with dysarthria, not with sensory aphasia.

If the abscess is located in the cerebellum, there may be, in addition to the general abscess symptoms, cerebellar ataxia, a diminution or increase of the deep reflexes, abducens paresis or palsy, acoustic nerve symptoms, and possibly cerebellar seizures. If the lesion is in some other part of the brain the symptoms due to involvement of that special portion, provided it is not a silent part of the brain, will be present in addition to the general symptoms referred to before. The motor area is so rarely the seat of otitic brain abscess that Koerner doubts whether it ever occurs. Our second case is important because it proves that an undoubted otitic abscess may involve the motor area. In the diagnosis of brain abscess in this region, doubt may arise as to the site of the abscess because of the relatively slight intensity of the localizing symptoms; there may be paresis instead of paralysis, and the deep reflexes may be less exaggerated than we are accustomed to find them in cases of solid neoplasm in this motor area. The explanation of this is found in the fact that an abscess is, after all, a more or less elastic and yielding foreign body, and does not exert the amount of pressure which a solid neoplasm of the same size would. Moreover, it is very evident that an abscess may develop near brain tissue without actually destroying it. Thus, in our second case, the symptoms were so slight that it was astonishing at the time of operation to find an abscess of considerable size. If the abscess be near the surface or if it merely press upon the surface, it evidently acts as a soft substance pressing upon soft tissues and thus causing relatively slight pressure symptoms. It is also surprising to note the rapidity with which symptoms are recovered from after the abscess has been evacuated and pressure relieved.

The two cases to be reported this evening are briefly as follows:

Case I. On May 23, 1906, Dr. Sachs was asked by Dr. Chas. Goodman to see Mrs. F., 42 years old, who had suffered from left-sided chronic otorrhea

*Read at a meeting of the New York Neurological Society, December 1, 1908.

for many years. The discharge from this was never very profuse. It was intermittent and of a seropurulent character. She had never had any pain in her ear or in the mastoid region. There had been an intermittent discharge for a number of weeks prior to the present illness. The family physician stated that on May 5, 1906, she complained of headache, nausea, and vomiting. The latter did not seem to be projectile in character. She had no dizziness, fever or chills. Between May 5 and 20 she was more talkative than usual, but was always rational. On May 20 she complained of headache, and on the afternoon of that day it was evident that she had forgotten the names of people in her home. The difficulty of speech increased, and in the evening it was apparent that she did not answer questions addressed to her; it was not observed at the time that this was due, not to her inability to utter words, for she spoke freely enough, but to the fact that she evidently failed to grasp the questions addressed to her.

Her physician found her in a condition of semistupor with slight rigidity of the neck, a slight degree of right facial paralysis, and some weakness of the right upper and lower extremities, and with increased reflexes in the right arm and leg. Her pupils were equal and reacted to light. There was no paralysis of the ocular muscles, but there was a slight optic neuritis. A careful examination of her speech disturbance on May 23 showed distinctly her inability to comprehend speech. Spontaneous speech was correct enough, though she occasionally used words which she did not intend to use—a form of paraphasia—but she failed absolutely to respond to such ordinary requests as to close her eyes, to grasp the hand, to flex the fingers, to frown, etc., thus showing that she did not understand questions addressed to her.

At the time of our first examination she was slightly somnolent and had the appearance of a person suffering from intense localized headaches. There was no ear discharge at the time, but examination of the drum showed a number of old scars. The history of chronic otorrhea, the optic neuritis, the headache and vomiting, the sensory aphasia and the paraphasia, together with the weakness of the right upper and lower extremities and the increased reflexes in these, together with absence of convulsive seizures, led to the diagnosis of a deep temporosphenoidal abscess of the left side encroaching upon the motor fibers in the internal capsule. At the time of operation all these diagnostic points were fully substantiated. On May 24, 1906, the day following Dr. Sachs' first examination, the operation was undertaken by Dr. Berg. Although there was no external evidence of mastoid affection, this bone was first of all exposed and opened. All of its cells had been obliterated, and its structure was sclerosed and very dense. The sinus was exposed and was seen to be immediately behind the wall of the bony meatus. The antrum was entered with a probe, but as its complete exposure would have entailed a very slow and laborious dissection of the sinus, and in view of the fact that no evidence of disease was seen in the mastoid or antrum, it was decided at once to proceed to deal with the cerebral condition. The mastoid incision was therefore prolonged upward and forward in a curved direction, so as to expose the squamous portion of the temporal bone, and the soft parts and periosteum were retracted from this over a space of 1½ inches in diameter. Starting from the roof of the antrum and tegmen tympani, the squama was removed with chisel and forceps over an area as outlined above. There was no visible cerebral pulsation, but the dura bulged considerably. With a large-sized trocar aspirating needle, a puncture was made into the temporosphenoidal lobe. About one inch beneath the cortex, two drams of seropurulent fluid were aspirated, and this was followed by a thick, creamy pus. The needle was left *in situ*, the dura was incised for about one-half inch alongside of the needle, a curved director was passed along the needle into the abscess cavity, and then the opening was enlarged with a dressing forceps. About two ounces of thick, creamy pus were evacuated. Drainage was established at the most dependent point by a soft rubber tube and two narrow strips of plain yellow gauze. Closure of the soft parts was affected down to the emergence of the drain. A dry aseptic dressing was applied.

The patient was not at all shocked by the operation, during which there had been very little hemorrhage. The next morning the patient's sensorium was much clearer. She was able to talk and recognized familiar objects, though unable as yet to name them. In the afternoon she was able to name some things, such as glass, spoon, and the parts of her body. Rapid recovery took place and, contrary to expectations, the aphasia had entirely disappeared within 48 hours; likewise, the weakness of the extremities and the right facial paralysis. The drainage tube was removed after ten days. The abscess cavity rapidly contracted and the patient was discharged cured after three weeks.

The patient was seen repeatedly after this and was always found to be in perfect health. There is no ear-discharge; the defect in the squama of the temporal bone has been almost entirely filled in by new bone. There is no hernia cerebri.

From a neurological point of view the points of special interest in this case are these: On account of the slight involvement of fibers coming down from the motor area the subcortical location of the abscess was correctly surmised. The rapid recovery from the speech defect and the disappearance of the motor paralytic symptoms in the extremities were astonishing. This cannot be interpreted in any other way than that in a slowly growing abscess, as this one surely was, the cortical centers and the fibers leading from them to deeper parts may be either only indirectly affected; may be dislodged rather than destroyed, and with the evacuation of the pus the dislodged parts resume their normal function. Even if one were willing to suppose that the right half of the brain had assumed some of the speech functions, in the case of an abscess which must have lasted for some weeks or months, the paralytic symptoms in the right half of the body were surely due to involvement of fibers descending from the left motor area, and these must have been either compressed or slightly dislodged without having been at all destroyed, or else they could not have regained so quickly their normal function. In this instance the sensory aphasia and the paraphasia were important symptoms pointing directly to the involvement of the left temporosphenoidal lobe.

From a surgical standpoint this case is of interest because it enables one to discuss the best manner of approaching and draining temporosphenoidal abscesses, and cerebral abscesses in general. But it will be better to defer this special discussion until we shall have recorded the second case.

Case II. This patient came under our observation

at Mount Sinai Hospital, in the service of Dr. Sachs. The patient was an Austrian woman, aged 22. With the exception of the fact that an aunt had died of tuberculosis, and that three children in her immediate family had died in infancy, there was nothing of special note in the family history. The patient herself had had measles in childhood but no other acute infectious disease. She had suffered much from cardiac palpitation but had presented no other cardiac or pulmonary symptoms. It was entered upon our records that she had been operated upon three months previously at another hospital in this city for left-sided mastoid disease. On further inquiry we were told that she had been operated upon for acute mastoid disease, following which a second operation was done for sinus thrombosis. After this right hemiparesis developed, including the facial, and a brain abscess was suspected. The temporosphenoidal lobe was explored (evidently through the tympanum) but nothing was found. She was ill for six days before the operation and following this operation she made a slow recovery. One month later a third operation on the same mastoid was performed.

When she entered the hospital September 19, her chief symptoms were weakness of the right half of the face, of the right arm and leg, pains in the right arm and leg, and a distinct limping gait. We also ascertained that there had been some speech disturbance during the first eight days after one of these operations, but at the time of her entrance into Mount Sinai Hospital her speech was entirely normal. She was kept under observation for a period of two weeks until we could ascertain all the facts regarding the previous operations. During this entire period the condition remained practically unchanged. The patient was able to walk around, except that on one or two days she had distinct attacks of nausea and vomiting, with some tendency to somnolence.

The physical condition, as determined, was a distinct right facial paresis. She answered all questions distinctly and was clear mentally except that now and then she showed a tendency to slight drowsiness. She complained chiefly of "a loss of life" in the right lower extremity. Sensation in the right half of the body was unaltered. The right upper extremity was slightly contracted at the elbow; the fingers of the right hand were slightly flexed with moderate wasting of the forearm muscles and of the interossei. There was no increase of the wrist or elbow reflexes. The abdominal reflexes were lost on both sides. The grasp of the right hand was fair, showing a paresis but no paralysis. The right lower extremity was weak, not paralyzed. When lying in bed she was able to lift the leg a few inches from the bed. The right knee-jerk was lively; there was right ankle-clonus and the Achilles reflex was present. There was no Babinski. On the left side the extremities were entirely normal except that the left knee-jerk was almost as lively as the right. All the other reflexes were less marked on the left side than on the right. There was slight, double optic neuritis.

In view of the persistence of these symptoms and of the history of ear disease preceding the first operation, the diagnosis of otitic brain abscess was maintained, but the symptoms evidently pointed to an abscess in the right motor area involving chiefly the center governing the left upper extremity. The patient was transferred to the surgical wards to be operated upon by Dr. Berg. The details of the surgical procedure are as follows:

Under ether anesthesia and with the hemorrhage from the scalp controlled by a rubber elastic tourniquet, a large osteoplastic flap with its base below, was raised from the skull corresponding to the left motor and sensory areas. There was very little hemorrhage, and comparatively little shock, the blood pressure, taken with the modified Riva-Rocci instrument, remaining about 110 mm. Immediately after the flap was raised the blood-pressure fell to about 90 mm., and throughout the remainder of the operation it stayed at this point. On raising the bone flap, the dura bulged into the wound; there was neither respiratory nor cardiac pulsation. Palpitation elicited a decidedly fluctuating area, corresponding especially to the arm center, and aspiration at this point with a short, wide-calibered needle withdrew a creamy-white pus. The dura was here incised, and a large abscess cavity, holding approximately six ounces, was entered. It was entirely encapsulated and lay between the dura and the brain cortex. Its lining was a thick pyogenic membrane that could be easily wiped away from the surrounding tissues. The dura was freely incised, until the lowest point of the abscess cavity was reached; then, after a complete evacuation of the pus, a counter-opening for drainage was made through the skull and scalp, corresponding to this lowest point. The osteoplastic flap was replaced, the scalp sutured, and a dry dressing applied.

The postoperative course was entirely uneventful. The drainage of pus through the tube for the first few days was free, then the discharge became serous, and finally ceased. The bone flap and scalp healed by primary union, and the patient was discharged healed about four weeks later. Within a few days after the operation, the weakness of the right arm, leg, and face entirely disappeared, and the mental condition became normal.

The neurological interest of this case is limited largely to the question of the localization of the abscess. You will remember that in the first case described in this paper there were symptoms pointing to the involvement of the right upper and lower extremities, as well as sensory speech disturbance. In this second case the paretic symptoms of the right upper and lower extremity were distinct enough, but there was an entire absence of speech disturbance, although the original disease had involved the left ear. In view of this absence of speech disturbance it was natural to infer that the abscess was not in the temporosphenoidal lobe, where it had been looked for previously, but in the motor area; and the successful finding of the abscess at the time of the operation proved that this reasoning was altogether correct. This case also forms a marked exception to Koerner's rule that otitic abscesses are invariably in immediate proximity to the diseased bone. The only point on which there had been doubt was as to whether this abscess was subcortical or subdural. Dr. Sachs was inclined to the subcortical site because of the relatively slight degree of paralysis in spite of severe general symptoms, the general symptoms pointing to a relatively large abscess. It was instructive, however, to find that the abscess, and one of considerable size, proved to be subdural, a much more favorable site for an abscess than a subcortical one would have been, and the inference to be drawn as to the moderate development of the paralytic symptoms, is that a subdural abscess presses rather lightly upon the cortical tissues and may thus cause only very slight paralytic symptoms. It is well also to note that in this case the cortical

tissue was not extensively involved, and that the ordinary irritation symptoms, viz., attacks of Jacksonian epilepsy, were entirely wanting. This point would be one of some importance in the differential diagnosis between abscess and solid neoplasm. In this second case, as in the first, recovery was prompt and complete. The patient left the hospital after a few weeks entirely cured of her abscess and entirely relieved of her symptoms.

Surgical Comments.—When the surgeon is asked to deal with an abscess of the brain that is as accurately localized as was the case in our two patients, his concern is entirely with the technical parts of the operation. He does not have to consider those technical details that must always receive attention when we open the skull for exploratory purposes. His concern is to approach the abscess by the most direct route, evacuate the pus, and establish satisfactory drainage of the cavity. It is evident that in any case there are three main considerations:

1. A wide exposure of the area of the brain in which the abscess is supposed to lie. This is best done by raising an osteoplastic flap. Some otologists, when operating for temporosphenoidal abscess, are in the habit of removing the bone in that region with rongeur forceps, thereby creating a defect in the skull. There are numerous objections to this procedure, the chief being that the exposure of a large area demands a wide removal of bone, and further, that such a large defect predisposes to the development of cerebral hernia. Again, it is a more time-consuming procedure than is the raising of the osteoplastic flap.

2. The second, and a most important consideration, is the protection of the meninges against infection by the purulent contents of the abscess cavity. If this lies near to the cortex of the brain, or upon it, it is more than likely that the meninges will be protected from infection by a barrier of natural adhesions that have formed before the operation is done. These are the most favorable cases for surgical interference. When, however, the abscess lies deep within the substance of the brain and there is no such barrier of natural meningeal adhesions, the question arises—Is it not preferable to operate upon such cases in two stages? In the first stage open the skull and incise the dura, and by gauze packings around the margin of the dural incision establish a barrier of protective adhesions between the pia and the dura mater, and at the second sitting which might take place after twenty-four hours, incise and properly drain the abscess cavity.

3. The third consideration for the surgeon, is the proper drainage of the abscess cavity. Here we must remember that there are two entirely different kinds of abscess cavities in the brain—one, with soft walls that readily collapse when the contained pus is evacuated; and the other with rigid walls that show no tendency to fall together, and that must be obliterated by the slow process of granulation. It is evident that an entirely different method of drainage must be employed in these two types. In the former, all that is required is the establishment of drainage by a thin slip of rubber tissue at the most dependent point of the cavity. This is to be removed after forty-eight hours, and not re-inserted. The opening in the scalp and skull, however, should be maintained by a piece of gauze packing, so that if pus or other secretion be retained, it will find its way out along the tract established by the rubber tissue. In the latter type of abscess cavity, the drainage must be by a tube of some kind, whether rubber or decalcified bone, or other material—according to the choice of the operator. This tube must be inserted at the lowest point of the abscess cavity, otherwise there is bound to be retention of pus. Inasumch as gauze ceases to act as a drain a few hours after its insertion, its use for drainage of such thick-walled brain abscesses is inadvisable. When the abscess occupies the temperosphenoidal or occipital lobe, or the cerebellum, the drainage of the most dependent part of the abscess cavity is easily esetablished through the primary wound, because this already lies at a point below the most dependent part of the abscess. This does not obtain, however, when the abscess occupies the frontal or parietal lobe. In such cases the abscess is approached from the higher parts of the cranial vault, and its lowest part is often one or two inches in the depths of the brain, considerably below the lowest point of the primary wound. If we wish to establish satisfactory drainage under such conditions, it must be done through a counter incision, the site of which corresponds to the lowest point of the abscess cavity. This incision may be made at the time of the primary operation, if the patient's condition warrants it, or at a later period.

The last point is well illustrated by a recent case:

Case III. Harry I., 25 years old, during July last while at Liberty, New York, sustained a compound depressed fracture of the skull, with laceration of the dura and brain, in the left frontal region. He was operated upon at once by a surgeon at Liberty. The depressed fragments of bone were removed and the lacerated dura and brain drained. Six weeks later, when he came under Dr. Berg's observation, he presented evidences of left frontal-lobe abscess. Exploration of this part of the brain revealed an abscess in the substance of the frontal lobe about one inch below the cortex, and extending downward toward the base about one inch. The cavity was drained by rubber tube which emerged on the convexity of the skull. It was thought by placing the patient in the Trendelenburg position, with much dependent head, that gravity would aid in establishing satisfactory drainage. This was not found to be the case. In the first place, the patient could not be kept in the Trendelenburg position for any length of time, and, furthermore, such position did not succeed in preventing retention and renewed signs of abscess formation. It was therefore determined to counterdrain the cavity through an incision just above the left frontal sinus, which was the level of its lowest point. Since this was done the patient has steadily improved and is now on the road to recovery. The abscess cavity is slowly filling with granulations.

For years past we have had but one fear in the treatment of brain abscess, and that was the question of drainage subsequent to the operation. This fear was largely based upon an experience which one of us had at the hospital a number of years ago in the case of a brain abscess in the motor area, following upon empyema, in a child. The abscess was in exactly the same location as in the second case reported in this paper. The child did unusually well for three or four weeks and subsequently died of a gradual purulent convexity meningitis, due to the difficulties of protecting the meninges against infection.

Abscesses in the temperosphenoidal lobe are so fortunately located that drainage there can be established readily enough. With abscesses in the motor area the problem is a much more difficult one,

and the successful management of these cases will no doubt depend upon the points advocated in this discussion of this subject by Drs. Whiting, Dench, Gruening and others. We trust that not only the cases herewith reported, but the entire discussion of the evening, will put prominently before otologists and surgeons this one proposition, that the successful treatment of brain abscess is chiefly a question of proper drainage.

ADEQUATE DRAINAGE THE ESSENTIAL STEP IN THE SUCCESSFUL SURGERY OF BRAIN ABSCESS.*

By FRED. WHITING, M.D.,
NEW YORK.

To those practitioners of medicine who interest themselves in intracranial surgery, it has long been a source of mortification and disappointment that after a brilliant operation, resulting in the evacuation of an abscess of the brain which has been accurately located by painstaking and masterly diagnosis, the condition has none the less in a large percentage of cases resulted fatally.

In abscesses situated elsewhere about the body the evacuation of their purulent contents is, with rare exceptions, the assured means to uniform and speedy healing, and we experience no apprehensions concerning a satisfactory result; but in dealing with abscess of the brain, the situation of the lesion, and the character of the tissue involved entirely alter the nature of the prognosis and the gravity of the condition still remains acute, notwithstanding that evacuation of the abscess has been accomplished.

In the opinion of the writer, the post-operative treatment of brain abscess has never received at the hands of general surgeons and otologists the consideration to which the importance of the subject entitles it. There are few more impressive or brilliant performances in surgery than the correct localization and prompt evacuation of an abscess of the brain, and there are probably but few occasions in a surgeon's career when he feels a keener sense of complacency and selfesteem than when with apparent confidence he plunges his bistoury into the brain and sees with a thrill of satisfaction which he scarcely dares credit a stream of pus follow his fortunate stroke. But with the completion of this brilliant surgical feat, the engrossing interest in the case oftentimes wanes, and the zeal which inspired our efforts on behalf of the patient while he was still an operative problem is apt to flag during the days of weary bedside mistration which must inevitably supervene before we can reasonably expect to see the fruition of our efforts in a fully established convalescence. It is the vexatious question of after-treatment that confounds our skill and sets experience at naught.

To summarize the situation, then, we are compelled to admit that our present knowledge of the after-treatment of brain abscess is not sufficient to warrant us in anticipating recovery in any given instance, but we must regretfully acknowledge that there is still a far cry between the moment of the successful opening of the abscess and the day of the complete healing of the wound.

Several years ago I became convinced that the method employed in dressing brain abscesses added very considerably to the gravity of the patient's condition, and to the percentage of mortality as well. My attention was called to this fact because of the observation that case after case of acute brain abscess would die after appearing to be doing very well for several days succeeding an operation which had relieved the patient, temporarily, at least, of the most urgent and threatening symptoms. After a few dressings there would gradually appear the characteristic manifestations of acute purulent encephalitis, which thereafter progressed rapidly until meningitis or ependymitis supervened and death ensued. I was accustomed at first to consider that infection had spread from the abscess cavity by means of veins or lymphatics which had undergone erosion as the result of unavoidable extension of the purulent process into contiguous tissue, and I did not then appreciate that faulty technique was to any great extent responsible for the mishap.

The findings of two autopsies, however, furnished valuable food for reflection, for, in each instance when the brain was cut and the abscess exposed there appeared discolored and softened areas of brain tissue radiating from the abscess wall and the drainage channel at varying angles and extending to various depths, with infected areas corresponding to fistulous paths and sinuses which had been made in the course of dressings in attempts to introduce gauze into the abscess cavity along a canal which could not be inspected. These infected tracts had been made after the same manner as false passages are produced in the urethra by misdirected sounds, after seeing which I realized for the first time how probable it was that faulty technique had contributed to a considerable extent to the unexpected fatalities in those cases which had appeared so promising immediately after operation.

That laceration of the brain should ensue upon an attempt to introduce gauze into the abscess cavity through a narrow opening and along a channel the walls of which are collapsed and in contact when not supported and separated by retaining gauze, a careful consideration of the anatomical relations will show to be nothing more than might be reasonably expected.

An acute brain abscess has a limiting wall of fibrin of such delicate texture and scanty resistance as to offer, after evacuation of the abscess contents, little or no opposition to the tendency of the brain with its soft, pulpy consistence, to collapse the walls of the abscess and prolapse toward the opening made in the dura at the time of operation, under which circumstances any attempt to introduce gauze drainage by the usual method is attended with serious risk of making a false passage with the probe and gauze, thereby conveying infective material into hitherto entirely healthy brain structure. That such an experience is most likely to result, observations upon the autopsied brain have satisfactorily demonstrated. It is a very simple matter to introduce gauze through a small opening, beyond which one cannot see, into a cavity with rigid walls in such a manner as to entirely fill the space and so dispose the gauze as to maintain uniform pressure upon all sides; but it is an entirely different proposition to carry gauze to the bottom of a deep cavity the opening of which is small and the channel leading down to which is narrow with delicate walls which will be wounded or lacerated at any point where the probe carrying the gauze deviates in the least from the direction of the passage for discharge from the abscess cavity.

With the hope of reducing and, if possible, eliminating from the post-operative treatment of brain abscess this dangerous and unnecessary traumatism,

*Read at a meeting of the New York Neurological Society, December 1, 1908.

I several years ago devised an instrument which was called an encephaloscope. This appliance was designed to permit, with the aid of artificial illumination, the critical inspection of the interior of a brain abscess cavity in such a manner as to avoid all violence to the brain tissue. Moreover, by the employment of this instrument the introduction and proper adjustment of gauze or other drains in the depths of the wound, both at the time of operation and during subsequent dressings, became an exceedingly simple and altogether safe procedure.

In this connection, the question naturally arises why not introduce a permanent tubular drain at the time of operation, and gradually withdraw and shorten it as the deeper parts of the wound heal, until only a shallow granulating pit remains, which requires no further drainage? Such a method would greatly simplify the after treatment, and remove the risk of infection by probe puncture. The reply to such a question revives a long and unsatisfactory discussion as to the relative merits of gauze versus tubular drains—a subject which will receive its proper consideration in another part of this paper.

Under the subject of drainage the entire consideration of the surgical treatment of brain abscess may be comprehended, for it properly includes the steps instituted for the thorough evacuation of the abscess at the time of operation, quite as much as the measures to be employed in maintaining an unobstructed outflow of the discharges from the wound during the period of convalescence and recovery.

The first essential step in abscess drainage is to secure complete evacuation of all purulent contents. That this may be properly accomplished, all obstructive bands of fibrin and necrotic tissue must be removed, and any communicating collections of pus made tributary to the drainage channel, since failure to remove such foci is responsible for the formation of the so-called multiple abscesses which are later discovered, and from the disastrous consequences of which the patients sometimes escape, when they are so situated as to admit of successful counter-drainage, but to the effects of which they more often succumb.

The careful personal study of the physical characteristics and structural conformation of brain abscess cavities, such as is readily obtainable by the use of the encephaloscope, has convinced me that great stress should be laid upon the importance of thorough evacuation of the abscess at the time of operation. We must bear in mind that in the brain we are dealing with an exceedingly soft and unresisting substance, which is disposed within a short time after an abscess has been opened to collapse upon and fill the space previously occupied by the purulent material just evacuated, and also to prolapse toward the opening in the dura and skull. As a consequence of this disposition, the collapsed fibrin-coated walls come in contact, and not infrequently adhere at one or more points between the bottom of the abscess cavity and its opening in the dura. As the result of this adhesion there becomes incarcerated in the deeper portions of the wound a certain proportion of those pyogenic products which should have been removed at the time of operation, and which with proper methods of procedure would have been removed. Such infective material walled off from the drainage canal will speedily institute further infective processes, to which the soft brain tissue falls a prey, and while the patient appears for a few days to be making uneventful progress, and the scanty discharges from the drainage canal encourage us to hope for a favorable issue, the undrained portion of the abscess continues to invade the brain more extensively and is later discovered as a result of further exploration undertaken for the relief of the patient from increasingly grave symptoms.

Or, perhaps, it is unfortunately discovered only at the autopsy, in which event we contribute to our selfesteem and to the inaccuracy of brain abscess statistics, when it is chronicled as a multiple or communicating abscess, although it is in reality nothing more than an unrecognized residual collection of pus, a mute and mortifying protest against our incomplete and unscientific technique. Those of us who have had to do surgically with abscesses extending deeply into the brain know that it is not a simple matter to ensure complete evacuation of the contents at the time of operation, for after the first gush of pus escapes the remaining contents present in the opening, and pulsate and throb, but do not escape, and although upon making expressive pressure upon the dura both laterally and from below an additional quantity is expelled, there still remains in a deep abscess a surprisingly large quantity of retained pus.

What measures then are customarily employed to accomplish the first essential step in abscess drainage—namely, the complete evacuation of the purulent contents? It has been the practice of some surgeons, after pus ceased to flow from a brain abscess, to introduce forceps of one kind or another, and by opening the blades to divulse the wound, and in this manner to assist the flow of pus which is usually retarded or obstructed by shreds of fibrin and necrotic tissue. Others, again, prefer to use the finger, considering that investigation by that member is safer and more intelligent than instrumental exploration. There are still other operators who deem it expedient to assist the removal of retained pus and other infective material by irrigating the cavity with a solution of boric or salicylic acid, or saline solution—such, indeed, being the practice of Macewen. Against each of the above-mentioned methods there is objection to be raised, and against irrigation especially, for if it be employed in acute abscesses, even with the most scrupulous care, there is danger of rupturing the walls of the abscess and of disseminating infective material into healthy adjacent structures. Irrigation of brain abscesses is, in my judgment, limited in its utility to the chronic variety with dense and firm walls, and even under these conditions the greatest caution must be observed in its employment. When the abscess cavity is very large, there is often but a thin layer of white matter separating it from the laterial ventricles, and even a very moderate force imparted to the irrigating stream might cause rupture into the ventricles. It is, indeed, no uncommon experience, when introducing gauze packing into a deep abscess without the assistance afforded by the encephaloscope, to puncture the ependyma and cause evacuation of the ventricular fluid, thus adding an unnecessary amount of risk to a condition already sufficiently grave. Exception is taken to the other above-mentioned methods of emptying the abscess cavity because they must be carried out without visual aid and are likely to cause injury, particularly if the cavity be deeply situated.

To the encephaloscope, however, none of the foregoing objections can be justly raised, for it does not subject the tissues to any traumatism whatever, requiring no greater force in its introduction than

a simple introduction of the finger demands, and being entirely free of the objectionable features of the divulsing forceps. As soon as the abscess is distended, its contents well up within the instrument and are mopped out with soft cotton or gauze pledgets, affording a comprehensive view of the interior, in the same manner as a speculum permits of an examination of the fundus of the ear. The three former methods—in addition to subjecting the brain to additional traumatism—are not by any means convincing in their dtmonstration of complete evacuation of the abscess, while the encephaloscope, introduced slowly, by degrees exposes to critical investigation every portion of the abscess, from the opening in the brain cortex to the bottom of the cavity, and if any pockets or subdivisions exist they are readily recognized and can quickly be made tributary to the principal cavity. The procedure is one of the utmost simplicity, and when properly performed offers entirely satisfactory evidence that the evacuation of the contents of the cavity of the abscess is complete.

With the aid of the encephaloscope, then, the cavity of an acute brain abscess can be quickly cleared of all gross or macroscopic infective material, but with the chronic abscess it is necessary to leave in situ the thickened capsule to slowly undergo sloughing, absorption, and organization. The temptation to use the curette upon the sloughing walls of a chronic brain abscess is almost irresistible, particularly since the encephaloscope affords so excellent a view of every part of them and the procedure, could it be performed with sufficient thoroughness, would undoubtedly materially reduce the difficulties and duration of treatment. There seems to be no positive contraindication to such a step, if undertaken with great care and delicacy, and with satisfactory illumination, except when the bottom of the abscess sac lies in close proximity to the ventricles, under which circumstances any attempt at curetting would be hazardous in the extreme. In judiciously selected cases, however, when the abscess is favorably situated—not too deep—it seems to me that curetting of chronic brain abscess where the lining membrane is very thick has little to condemn and much to commend it. In any event, when large tufts of necrotic granulations are seen upon the abscess wall, they should be scraped away lest, by remaining, they be permitted to conceal a path of infection already extending into adjacent brain tissue.

When the abscess cavity has been cleansed as thoroughly as circumstances permit of all infective material, the next step in the procedure is to determine the character of drain to be employed. What material will make the most effective drain? In this selection we are limited in our choice to tubular or fixed drains, and gauze or renewable drains—the cigarette or rubber tissue drain not being applicable to the conditions. In England and upon the Continent, tubular drains have been preferred and many varieties have been recommended, including soft and hard rubber, glass, pressed wood fibre, decalcified bone, and other materials, and each has enjoyed a certain measure of success. Macewen has shown a preference for decalcified turky bone, and most continental operators for fenestrated soft rubber. In this country, however, such drains have not been received with great favor among surgeons who have done most of the operating, and gauze has practically superseded all other materials for purposes of drainage, with recent results quite as successful as those of our European colleagues.

As regards the relative merits of gauze and tubular drains, there is in small and superficial brain abscesses but little choice—either answering the purpose admirably, although for the tubular drain the theoretical advantage is claimed that its employment admits of suturing the dural incision and the scalp as well, thereby reducing the likelihood of cerebral hernia, although under the conditions mentioned the probability of hernia is slight. As far as my personal preferences are concerned, I have discarded all other drains in favor of sterile or iodoform gauze, in the firm conviction that there is nothing accomplished by tubular drains in any abscess dressing which gauze properly adjusted will not accomplish at least as well, and in many cases a little better.

Having determined upon the use of gauze for the drain, the method of introduction becomes a very simple matter, but I am convinced that the method employed in dressing acute brain abscess should differ materially from that followed in chronic brain abscess. In acute purulent encephalitis, after the pus has been once fully evacuated, it seldom reaccumulates in large quantities except where there has been extension of the infective process into contiguous structures, and since the amount of fibrin is very scanty, not constituting in any case so far observed anything near a complete investing or lining membrane, there is but little material present in such an abscess which should unduly prolong suppuration or delay repair. It seems wise, therefore, in such an inflammation, to reduce the gauze packing to the very least thread which will maintain a pervious channel to the bottom of the abscess and conduct to the surface such scanty discharge as a healthy granulating tract supplies, but under no circumstances to introduce sufficient gauze to distend or balloon the abscess cavity, for such distension serves no purpose other than to maintain needless and harmful increased intracranial pressure, and to contribute to the risk of cerebral hernia.

The requirements of the acute condition I have found to be best satisfied by the introduction to the bottom of the cavity of a single wick of iodoform gauze, of the size of a lead pencil, which dressing is to be changed at intervals of forty-eight hours, until the surface exposed to view by the encephaloscope is seen to be covered by a layer of small pinkish granulations. As soon as this appearance, which sometimes supervenes in an amazingly short time, is manifest, the length of the gauze drain should be decidedly reduced and the depths of the abscess permitted to heal, preliminary to closure of the drainage channel from the dura inward. It not infrequently—in fact, usually—happens that a small cerebral hernia is found protruding through the dural opening, and before the encephaloscope simplified the method of treatment so materially, such an accompaniment of brain abscess constituted a decidedly annoying and sometimes most embarrassing complication. Under the present conditions, however, but little concern is occasioned by the presence of hernia, unless it be of extraordinary size, which it seldom is—for as healing progresses it gradually shrinks, being in part strangulated by the contraction of the cicatrix which closes the opening in the dura and causes sloughing, and in part absorbed by and incorporated with the scar tissue which ultimately constitutes the tegumentary coverings of the field of operation.

I would advocate in chronic brain abscess a method of post-operative procedure which is the direct antithesis of that which has afforded such satisfactory results in acute processes. In chronic brain abscess there is present a dense, firmly-resisting fibrinoplastic membrane which must slough away or undergo absorption before the abscess channel may with safety be permitted to close. The process of sloughing is apt to be protracted, and is accompanied by a profuse purulent discharge which accumulates with such rapidity and often exhibits such putrefactive properties as to render daily dressing imperative. To an operator whose experience is limited to acute processes only, the quantity of offensive pus discharged from a chroinc abscess in the short space of twenty-four hours is a source of astonishment, and must be encountered in order to be appreciated. In the first few daily dressings of a large chronic abscess the amount of discharge almost suggests the existence of a communicating abscess which is contributing to the extraordinary supply by draining imperfectly into the cavity of the abscess which is under observation, and it is not until the thick capsule-like lining of fibrin begins to slough and undergo organization that any sensible diminution in the quantity and alteration in the character of the discharge is apparent. The condition is somewhat analogous to an extensive subperiosteal mastoid abscess, the purulent contents of which have been evacuated by simple incision, leaving the walls, which are lined with necrotic granulations and fibrin to the slow process of gradual sloughing and organization, instead of opening the sac widely, everting the flaps, and subjecting the infected surfaces to a vigorous application of the curette, which would simplify the healing amazingly.

I believe that it is necessary in the operative and subsequent daily dressings of chronic brain abscesses, first to mop the cavity thoroughly with sterile absorbent cotton, and then to introduce sufficient iodoform gauze to distend or balloon it, a practice which must be perservered with until all fetor disappears, the discharge is diminished greatly, and the former fibrin-coated suppurating surface is covered with small red granulations, with the appearance of which manifestations favorable and speedy healing may be anticipated.

Concerning the dressings which are to be made during the after-treatment of the case, they are in the main simple repetitions of the practice first described, with such modifications of detail as the changing conditions of the wound demand and experience dictates. Eternal vigilence is the price of success in treating brain abscess, and the least unfavorable manifestation in the patient's condition should lead to a critical inspection of the wound.

A profuse purulent discharge, persisting more than a few days after operation, or appearing in the course of treatment of an acute abscess after there has been but a scanty discharge for some days, may be accepted as an infallible indication of extension of infection into tissues hitherto healthy, and as a rule, with the appearance of such local warnings systemic disturbances are not long delayed. An experience of the kind just described is unfortunately not an infrequent complication of brain abscess, and failure to respond favorably to frequent changes of dressings, will necessitate the performance of counter drainage. This procedure, if practicable—that is, if admitting of the necessary delay—should be undertaken after the manner suggested by Ballance, who advises that at the point selected for the counter-opening, the dura and superficial brain tissue beneath it be incised and lightly packed with gauze for a sufficient time to permit the membranes to become adherent to the brain about the opening, thus sealing the subdural space against infection, when on the following day the counter opening is carried through the deeper brain tissue and communication with the abscess established, and counter drain introduced.

The necessity for counter-drainage is greatly to be regretted, and I am fully persuaded that the employment of proper technique for the complete evacuation of the abscess cavity at the time of operation will greatly reduce the frequency of the performance of such a hazardous expedient.

I have often been asked how we are to decide when drainage of the abscess cavity may be safely discontinued. In reply, I would say that the drains should be used as long as there is any recognizable purulent discharge from the wound. As soon as the abscess wall begins to granulate nicely, which is oftentimes a matter of a few days only, the gauze wick upon being withdrawn will be found to be soaked with serum and practically free from pus. Under such circumstances only a very short strip of gauze should be introduced, and within a few days thereafter all drainage discontinued.

Another frequent inquiry is as to whether or not it is wise to employ irrigation at any stage of the treatment of brain abscess. I can only reply that in my judgment it is a dangerous expedient which had better be dispensed with, except in encapsulated abscess; and I cannot comprehend how any surgeon who has ever inspected the extremely delicate walls of an acute abscess by the aid of an encephaloscope can be willing to assume the risk of disseminating infective material into the healthy brain substance by employing even the most gentle irrigation.

Still another query which has been asked is—Does one learn much from introducing the finger into an abscess cavity? Without hesitation, I reply, No! The information elicited by digital exploration of the abscess is at best but a very unsatisfactory substitute for the unimpeded inspection afforded by the encephaloscope, and furthermore it adds to the danger of infection. I recently attempted at the Morgue to convince myself concerning the reliability of the tactile sense for the purpose of recognizing objects of different density within the brain tissue. For this purpose, I introduced by means of a long curved needle several parallel threads of different sizes within a fresh brain carefully avoiding any tension. After making an incision in the brain substance over the situation of these threads, the finger was introduced, but failed to recognize their presence until they were put upon the stretch. This experiment was repeated with coarser threads, which in turn the finger failed to recognize, until twine of the weight commonly used in stitching up the body after an autopsy was employed. Small pledgets of cotton similarly introduced could not be detected, even when the extremity of the finger came in direct contact with them. In other words, I was unable to detect the presence of any foreign material within the brain, until the density of such substance was materially greater than that of the brain in which it was embedded, which experience has not increased my appreciation of the value of digital examination for purposes of exploration in brain abscess. In this connection I would quote from a recent report of a successful operation for brain abscess done in my service at the Infirmary in 1904, by Dr. J. R. Page.

then House Surgeon. He says: "During my service at the New York Eye and Ear Infirmary, every case I saw in which the finger was introduced into the brain died." Such testimony is certainly not commendatory of the procedure.

There are many interesting and important considerations referable to the post-operative care of brain abscess cases, which the question of drainage naturally suggests, but which the allotted time and limited scope of this paper alike forbid me to mention. In closing the consideration of the subject at this point, I would emphasize the fact that three important details constitute the essential factors of successful abscess drainage:

1. Scrupulous care to be exercised in inducing complete evacuation of all pus and pyogenic material at the time of operation.

2. The establishment and maintenance of an uninterrupted communication, by means of gauze or other drains, between the deeper portion of the abscess cavity and the drainage opening, without adding unduly to the pressure upon the brain substance surrounding the walls of the abscess.

3. The avoidance not only at the time of operation but especially during the after treatment of gratuitous infection of healthy surrounding brain tissue by misdirected efforts at the introduction of gauze or other drainage material attempted without the assistance of actual inspection of the abscess path.

With a proper appreciation of the importance of these essentials, and a rigid attention to the details necessary for their correct performance, I am well convinced that we shall save many lives which, notwithstanding the promise of a brilliant operation were formerly lost, a mortifying sacrifice to the avoidable errors of after treatment.

CLINICAL AND ANATOMICAL MANIFESTATIONS OF OTITIC BRAIN ABSCESS.*

By ALFRED WIENER, M.D.,

NEW YORK,

ATTENDING OTOLOGIST AND LARYNGOLOGIST TO THE SYDENHAM HOSPITAL.

The occurrence of brain abscess after purulent otitis media is rather a serious complication. Its localization, as well as its early recognition, is an urgent matter, but often a difficult task. Such abscesses follow both acute and chronic otitis media purulenta, especially the latter. According to statistics as published by Grunert, in 91 per cent. of the cases the abscess was due to a chronic suppuration of the middle ear. Hammerschlag, on the other hand, finds only 75 per cent. due to this cause. In regard to their relative frequency, Jansen reports one brain abscess in 2,560 cases of acute, and six in 2,500 cases of chronic, suppurative otitis media. As to the age of the patient, we find otitic brain abscess in early childhood rather seldom. This appears strange, on account of the numerous dehiscences, fissures, and direct paths of communication in the child's skull. The largest number of otitic brain abcesses occur between the ages of ten and thirty years of age. They appear to occur more frequently on the right side, according to Koerner and Koch. On the other hand, Okada, Heimah, and Neuman, whose statistics refer especially to cerebellar abscess, place the percentage higher on the left side. Koerner explains his statistics as due to the fact that the transverse sinus on the right side is much more developed, lies deeper within the mastoid process and petrosal pyramid than on the left side. As a result of this, the bone separating an empyema of the middle-ear cavities, a carious focus, or sequestrum in the mastoid process, from the brain proper, its membranes, or neighboring blood-vessels, is much thinner on the right side than on the left. The difference in thickness between the two sides, according to actual measurements, may be between 1.05 mm. and 7 mm. All agree that cerebral abscesses are more frequent than cerebellar.

In the large majority of cases, otitic brain abscess will be found to lie in close proximity to the primary suppuration in the petrous portion of the temporal bone, very often in direct communication with it. Koerner gives to us the following table in connection with this fact: In 42 per cent. of the cases the abscess cavity in the brain was seen to be in close communication with the primary suppurative lesion in the bone by means of a fistula; 15 per cent. show the brain abscess and perforated dura in close association with the primary lesion; 26 per cent. show the membranes of the brain adherent to the diseased bone and the brain, and the abscess in the brain separated from this portion by brain substance; in 17 per cent. of the cases normal brain substance lies between the abscess and the diseased bone.

In regard to the location of these abscesses, in the majority of the cases the abscess lies in the temporosphenoidal lobe, when the suppurative process has broken through the tympanic roof. In the cerebellum, pons, or crura cerebri, when the posterior wall of the petrous portion of the temporal bone, or inner wall of the mastoid process is at fault. To speak more accurately of the location in the temporosphenoidal lobe, these abscesses are found in the posterior and inferior portion, the gyrus fusiformis, and sometimes, but seldom, in the occipital lobes.

In the cerebellum they occupy most frequently the anterior portion of the lateral lobe. They are found, however, also in the inferior semilunar and cuneiform lobes; sometimes in the tonsil, flocculus, and even in the middle peduncle of the cerebellum.

There are cases on record, two such I have personally observed, in which the abscess is located at some distance from the diseased temporal bone. I refer to the central convolutions. Koerner argues that these are really not otitic abscesses as we understand them, but caused only indirectly by the suppurative process in the middle ear. They are the result of pyemic conditions due to sinus phlebitis and to metastatic processes from purulent bronchitis. Often they are tuberculous.

Extradural abscesses are found between the bone and dura mater. In other words, a pachymeningitis purulenta is due to an extension from the ear sinuses into the skull cavity. They occur in the middle and posterior fossæ. Most frequently we meet such abscesses in the neighborhood of the lateral sinus, in which position we designate them as perisinus abscesses. Deep extradural abscesses have been found on the posterior surface of the petrous portion of the temporal bone, due usually to suppuration in the labyrinth, the infection finding its way out through the aqueductus vestibuli.

As a rule, brain abscesses are solitary. When multiple abscesses occur they usually break down into one abscess cavity. Two large abscesses close

*Read at a meeting of the New York Neurological Society December 1, 1908.

together are usually in communication with each other. In 100 cases collected from the literature by Koerner, fifteen showed the presence of multiple abscesses. In six of these, one abscess was found in the temporosphenoidal lobe and one in the cerebellum. In five, multiple abscesses occurred in the hemispheres. In four, multiple abscesses occurred in the cerebellum. Koerner rightly remarks, I believe, that under such conditions we are dealing with metastatic pyemic and pulmonary abscesses.

In regard to the size of the abscesses found, they vary from the size of an almond to that of a fair-sized chicken's egg. Usually they are about the size of a walnut.

The contents of most abscesses is pus. This may be of a fluid consistency or as thick as molasses. It is very often milky in color, sometimes green, sometimes yellow, and often a dark brown. At times there is no perceptible odor, and at times this is very fetid. Often there is mingled with this pus necrotic brain tissue, and at times blood in various stages of decay. Most brain abscesses are encapsulated. These are again surrounded by a softened infiltrated and edematous mass of brain tissue. The capsule is, in reality, a pyogenic membrane, usually very thin but it may be as thick as 5 mm. In old abscesses it is tough and often in a calcified condition. Leutert, as well as Bergmann, have called our attention to the fact that these capsules do not prevent the further extension of the abscess, which might occur at any stage of the affliction. In regard to the division of abscesses into parenchymatous and interstitial forms, as described by Mueller, this theoretical reasoning has been refuted by Preysing and needs only to be mentioned here.

As stated before, brain abscess is most frequently met with after chronic otitis media purulenta. In acute otitis purulenta the inflammatory process invades hardly more than the mucous membrane. Should the inflammatory condition, however, be of a severe type, and the infection a virulent one, thrombi form in the vessels of the mucous membrane, grow into the vessels of the surrounding bone, sinus, and brain membranes, and thus the infection is carried into the brain tissue. Right here I would emphasize a fact, which it would be well to remember, that we may have an acute otitis media, followed by caries and sinus thrombosis, without perforation of the drum membrane. Such a case I have seen personally, and such have been reported by Macewen, Schwarze, and spoken of by Neuman. It is well to bear in mind such cases in connection with obscure pictures of brain abscess, although no case of brain abscess is on record of ever having occurred after such a condition.

After chronic otitis media purulenta, a brain abscess is more naturally expected. First of all, the mucous membranes of the middle ear go through all the stages of a chronic inflammation. Its vessels, which are in direct communication with the bone, cause the infection to be carried to this part, and caries and necrosis is the result. The tympanic cavity, the antrum, and the mastoid process are successively involved. The inflammatory irritation causes granulation tissue to spring up, which fills the cavity of the middle ear. A stagnation of pus and secretion takes place. In spite of the fact that the antrum and tympanic cavity are enlarged through the breaking down of the bone and its septal divisions, it is nevertheless reduced in size, through the encroachment upon it of large masses of granulation tissue. In other portions there is a new formation of bone, the eburnizing process. We have therefore two processes at work, a destruction or necrosis of tissue, and a new growth or sclerosing process. Unfortunately the sclerosing process is no protection against the further advance of the necrotic process, as it does not always completely surround the necrotic area. Frequently an acute exacerbation occurs in the primary lesion through a recent infection, and the necrosis works its way through the tympanic roof or the walls of the antrum, or mastoid process, into the skull cavity. Such conditions we find most frequently with cholesteatoma, a process which, when it is known to exist with chronic otitis media, is in itself of serious import, and should be dealt with most radically. Schwarze tells us that his experience has taught him that the reason why infective processes in the middle ear at times produce diffuse meningitis, and at other times circumscript lesions like sinus thrombosis, brain abscess, or extradural abscess, is to be sought for in the virulence of the infectious agent. An infection of a mild type leads to an adhesion of the brain membranes, a shutting off, as it were, of the arachnoid space, and thus a barrier to diffuse infection. Infection produced by virulent organisms at once infect the membranes before such a barrier is formed.

Neuman believes that the preformed pathways are the cause of diffuse infection of the brain membranes, when the infection proceeds in this direction, and rarely the cause of brain abscess, unless the pathway happens to be the aqueductus vestibuli. On the other hand, when there is a destruction through caries and the formation of fistula, this rather slow process has a tendency to produce a circumscribed lesion, viz., extradural and intradural abscesses, including, of course, brain abscess. The intradural abscess or, as Macewen speaks of it, ulceration of brain tissue, occupies the median position.

Again, according to Preysing, the different courses pursued by the various brain abscesses depend not upon their anatomical localization, but upon the intensity of the inflammatory process, and the period at which it is recognized. With a high degree of virulence and a poor resistance on the part of the organism, the destruction of tissue advances rapidly, so that no encapsulation of the abscess is possible. With diminished virulence and good resistance, granulation tissue springs up and encapsulation results. Again it may be well to mention here that the infection producing a brain abscess is not always a direct one, but may be carried there through the lymphatics or by the way of the pial blood-vessels.

According to the statistics, as published by Hessler, abscess after chronic otitis media is found to be encapsulated in 65 per cent. of the cases. After acute otitis media, in 38.5 per cent. of the cases. The brain tissue immediately surrounding brain abscesses is usually found to be edematous and infiltrated with red blood cells, passing gradually into normal brain tissue. Encapsulation is not to be considered as preventing a further progression of the abscess. Such abscesses may be absorbed, or result in cystic or scar formation, or through an acute exacerbation of the original trouble or trauma, a further extension of the abscess may take place.

The clinical picture of brain abscess is a varied one. An extradural abscess may be present and not a symptom to account for it. Often these abscesses are only discovered during the process of an operation upon the mastoid bone. In extradural abscess all the symptoms of actual brain abscess may

be present, but they will usually be found to be very mild in degree. One of the most constant symptoms is headache over the diseased area, varying in quality and intensity. Optic neuritis is conspicuous by its absence. The local symptoms, when they are present, are rather more characteristic. In the region of the emissary mastoid vein, we have tenderness to pressure, edema, and at times the formation of a subperiosteal abscess. This is especially the case when the abscess occurs in the sigmoid fossa.

When the abscess occurs within the brain, symptoms present themselves which we may classify as general and local. The general symptoms establish the diagnosis that a brain abscess is present, and the local symptoms its possible location. Let us consider first of all the general symptoms. We may and we may not have a rise of temperature. Very often, in uncomplicated cases, the temperature will be normal or subnormal. Usually in the evening there is a slight rise. Oppenheim believes that continuous and marked rise of temperature speaks most probably against uncomplicated brain abscess, while on the other hand, a slight occasional rise of temperature favors brain abscess.

The pulse is usually slow and its tension increased. A pulse beat as low as ten pulsations per minute have been recorded by Schwarze. Then again, we may have a perfectly normal pulse. Jansen reports a case of large brain abscess without the slightest variation in the pulse rate. Schwarze is rather of the opinion that the pulse rate in some cases may be governed, not by increased brain pressure within the skull cavity, but by some toxic irritation of the vagus. He believes that this is also the cause of the double optic neuritis, which occurs in about one-fourth of the cases.

One of the most frequent, constant and earliest symptoms, is headache. It is usually constant, but varies in intensity. A very marked exacerbation takes place when there is a rise of temperature. As a rule, the headache usually localizes itself over the region of the abscess. But cerebellar abscesses have been known to cause frontal pain, and temporosphenoidal abscesses occipital pain. In regard to the tenderness on percussion over a brain abscess, Barker, Horsley, Macewen, and others, have frequently called attention to the circumscribed area, found just above the edge of the auricle, when an abscess exists within the temporo-sphenoidal lobe. Cerebellar abscesses have given us no hint of their presence through percussion.

Vomiting with and without nausea, upon an empty stomach, the well-known projectile cerebral vomiting, is rather characteristic of brain abscess. Vertigo is frequently met with in close association with the headache. Constipation in an individual who has not previously suffered with such a disturbance, and which proves stubborn to all cathartics, is a suspicious symptom.

Slow cerebration, with forgetfulness of important daily occurrences, a change in the character of the individual, who at one moment may be sad, silent, and morose, then suddenly becomes talkative, stubborn, and irritable, are characteristic symptoms. Frequently there is hypochondriasis with a tendency toward suicide. Delirium and maniacal attacks have also been seen.

The fundus changes, according to Macewen, are frequent but not constant. In the majority of cases a mild neuritis is present in both eyes. Seldom do we see the picture of a choked disc, as we find it in brain tumor. Usually it is more developed on the diseased side. It may be unilateral and occur only on the normal side. Optic neuritis is present in mild cases as well as in severe cases. Very often after the abscess is emptied, this neuritis may not disappear at once; in fact, it may progress for a time. There is never any marked disturbance of the vision and rarely does atrophy follow. With such symptoms we may imagine a clinical picture as follows: A patient with the history of suppurative otitis media presents himself. He appears frail, looks exhausted, and presents the appearance of a very sick man. His color is pale. He tells us that he is rapidly losing weight. His tongue is thickly coated. He is suffering with obstinate constipation. His headache is constant, excruciating, and localized. There is a slight rise of temperature with a slow pulse. He tells us that he has had several attacks of vomiting with vertigo. His slow speech, his miscomprehension at times of what is said to him, his forgetfulness, his desire to lie down and go to sleep, all these symptoms make rather a characteristic picture.

In regard to the local symptoms, we find that they present different pictures according to the location of the abscess in the middle or in the posterior fossæ. As it is not the purpose of this paper to go into this portion of the subject, the simple mention of the presence of local symptoms will suffice. It is well to call attention here to the fact that brain abscesses usually pass through four stages. These stages are recognized by most authors: An initial stage, a latent, a manifest, and a terminal one. The initial is of very short duration, and not characteristic. It shows itself by the presence of headache, vomiting, and fever, all of which symptoms might be accounted for by the primary ear condition. This stage passes rapidly into the manifest period, and not frequently into the latent. The latent period is characterized by symptoms of slight degree. Headache, depressive periods, and slight rise of temperature in the evening are in evidence. These the patient rarely notices, and the physician falsely interprets. This period may last a few weeks or as long as two years. The manifest period presents the symptom-complex of brain abscess. It usually lasts about two months, but it may continue for one year.

The terminal period is brought about by the increased brain pressure and edema with rupture of the abscess into the ventricles, or on the surface of the brain. This is often brought about through some mental excitement, or it may be due to a blow or fall upon the head.

The final outcome of uncomplicated brain abscess when uninterfered with is usually death. This is due to the increased brain pressure and edema, or progressive encephalitis followed by toxic coma, or the abscess may rupture into the ventricles or arachnoid membranes with the usual fatal consequences.

If certain matters pertaining to brain abscess in general have not been touched upon in this paper, it is for the simple reason that I wished to confine myself simply to otitic brain abscess. Furthermore, to call attention to only such conditions that bear upon and will help in directing the plan to be pursued when surgical interference is necessary. I would therefore like to emphasize the following points:

1. In those cases in which it can be demonstrated that suppuration is still going on in the middle ear, or contiguous parts, and one is reasonably sure that brain abscess complicates the condition, it is well to

remember that in 57 per cent. of such cases the brain abscess and the suppurative condition in the ear are in direct communication.

2. There are cases in which the suppurative process in the ear is active, but the abscess is separated from the primary suppurative condition by normal brain tissue. This occurs in about 26 per cent. of the cases.

3. The suppurative condition in the ear has ceased, and there is every reason to believe that a brain abscess is present and to be accounted for by this previous suppuration. The abscess may lie in close proximity to the original trouble or at some distance from it. In these cases no communication with the ear sinuses exists.

Numbers 2 and 3 are usually classified as metastatic abscesses and form about 43 per cent. of the cases that we meet with.

Finally, I would like to call attention to the fact that at times abscesses are latent and also may possess very thin walls. Furthermore, that they may be situated dangerously near the ventricles or the arachnoid space. In operating upon these cases, if the mastoid process is first attacked, the chiseling necessary to open these mastoids may lead to rupture of the abscesses with a rapidly fatal consequence.

Again, such abscesses may exist in the latent stage for a long time and become manifest after an ordinary trauma to the skull.

In all such cases, it is my firm belief that even though the abscess may be suspected, we should deal most radically with the suppurative ear condition first, and then boldly attack the abscess; my reasons for so doing being that, after all, while we are only suspicious of the abscess, and doubtful as to its exact localization, performing a radical mastoid may at once give us sufficient evidence of the presence of such an abscess and its exact location.

Taking these anatomical and clinical facts into consideration, in the treatment of otitic brain abscess, we should especially consider first the location of the abscess; second, its duration; third, its intimate connection with an existing suppurative process in the middle-ear cavity.

616 Madison Avenue.

PYLORIC STENOSIS.*

By JAMES SPENCER BROWN, M.D.,

MONTCLAIR, N. J.

SURGEON-IN-CHIEF OF MOUNTAINSIDE HOSPITAL.

The following paper is based upon the writer's experience in a class of cases which to him have been full of interest, because of the many difficulties in arriving at a correct diagnosis, viz., diseases in or about the pylorus, in which pyloric stenosis is a prominent symptom.

The surgical treatment of pyloric stenosis originated with Wolffer in 1881. Wolffer at that time was assistant to Billroth, and was engaged in operating upon carcinoma of the pylorus. Resection was found to be impossible, and Nicoladoni, who was acting as assistant, suggested the feasibility of attaching the jejunum to the stomach, so as to form a new outlet. This suggestion was acted upon, and a new lifesaving operation was given to surgeons, namely, gastroenterostomy. Because of the low mortality and the gratifying results when compared with pylorectomy, the operation at once became popular, and our present knowledge of the gross living pathology of diseases of the upper abdomen is based upon the information gained while performing this and gall-bladder operations.

The pylorus and duodenum have a fairly fixed anatomy, but the position of the jejunum varies in individuals and probably in the same individual at different times. The stomach, on the other hand, has a great motility. Its position varies according to its musculature, from a contracted organ lying back of the transverse colon in the lesser abdominal cavity, to an enteroptosis with dilatation in which it is found entering the pelvis. It can therefore plainly be seen that diseases affecting either of the organs give a great variety of misleading symptoms, and present a varied gross pathology. It necessarily requires a large number of observations and the combined work of physicians and surgeons to differentiate these various symptoms. Each year brings its store of information to the physician, gradually but surely allowing him to interpret the meaning of certain symptom-complexes. On the other hand to the surgeon each year brings experience in the gross pathology, and instead of recognizing only the late results of malignancy and peptic or duodenal ulcer, we now recognize other pathological conditions, quite distinct and apart, which produce either pyloric spasm or organic duodenal stenosis, namely, pancreatitis, appendicitis, etc. In looking back over my work, my sense of justice is somewhat shocked to find so many cases in which my inability to recognize the true condition led me into sins of omission.

Given a case with the typical picture of pyloric stenosis due to ulcer, hyperchlorhydria, dilatation, food stasis, pain, vomiting, and emaciation, with a previous history covering years or months of stomach trouble, no difficulty will be found in arriving at a correct diagnosis in a very large percentage; but unfortunately these pictures are seldom seen, and he is a wise and lucky surgeon who has not had what he considered a clear ulcer-picture before him, and operated only to be chagrined because of his inability to demonstrate a pyloric stenosis. And if he has been bold enough to do a gastrojejunostomy to cure a dilated stomach, his chagrin will deepen into despair when the patient presents himself weeks later, not only unrelieved of his symptoms, but with one added, namely, bilious vomiting due to regurgitation of bile through the stoma he has been good enough to add to the already diseased stomach.

It therefore seems necessary that the surgeon himself should be able to determine the value of symptoms. I have consequently been in the habit of studying the individual symptoms as well as the symptom-complex.

The first of these is *pain*. Upon looking over our case-notes, I find that pain was present in all cases of ulcer; in 40 per cent. of early cases of malignancy it was present; and in all the later malignant cases it was a prominent symptom.

Our experience leads us to believe that any stomach case, in which pain has been a long-continued symptom, not responding to proper diet and medicinal treatment, should be looked upon as a case to be investigated with a view of surgical interference. This does not mean that every case must be operated upon, as it is a well-known fact that the acute round ulcer will heal promptly in over 90

*Paper read before the Practitioners' Club, Plainfield, N. J., July, 1908.

per cent. of the cases when treated properly by diet and medicine. Of the 10 per cent. which do not respond to treatment at once, fully 5 per cent. heal in the hands of an expert, and the last 5 per cent. are ulcers of the lesser curvature or duodenum, and these are the ulcers that require surgical care.

The anemic dyspepsias occurring in underfed or pampered young adults, lasting over a period of time, and presenting the typical ulcer picture, must be differentiated and left severely alone.

In the so-called "hemorrhagic gastralgia" of Dawson, Herringham, Lejars, Mayo Robson, Monahan, and Frederick Smith, in which hemorrhage is added to the typical ulcer picture, as noted in the 20 cases operated on or coming to autopsy, reported by Hale White, no ulcer is found. These are possibly cases which need more investigation to determine the true pathology, like the hematemesis which was known to accompany cirrhosis of the liver and fought our best efforts for years. However, this rather rare disease, hemorrhagic gastralgia, is generally cured by gastrojejunostomy, because, as pointed out by Dawson, the alkaline secretion is added to the acid stomach through the stoma, relieving the hyperchlorhydria and also lowering stomach pressure.

It has been stated that lesions near the cardiac end of the stomach are associated with pain soon after taking food, while lesions about the pylorus produce pain long after ingestion of food. This statement, while logical, is not borne out by the facts. Of 60 cases investigated by operation or necropsy by Bertrand Dawson of London, in 23 pain occurred immediately upon ingestion of food, and in these 23 cases the lesions were divided as follows: 19 limited to the pylorus, 3 ulceration at the lesser curvature, while in one case nothing was found except pyloric adhesions (possibly pancreatitis).

In three cases where the head of the pancreas, bile ducts, and duodenum were bound by adhesive inflammation and where a tumor could be felt before operation, pain was not a prominent symptom. It may therefore be said that here, as in other regions of the body, pain depends upon the individual rather than upon the position or extent of the lesion. It may generally be said, however, that pain from chronic ulcer with stenosis is more intense than pain which accompanies early cancer.

Hemorrhage from the stomach may occur from acute round ulcer, chronic duodenal ulcer, cancer, saddle-ulcer, and hemorrhagic gastralgia. It may be alarming in amount or it may be microscopic. Its presence means erosion. Its importance depends upon its position in the symptom-complex.

Vomiting. In duodenal or peptic ulcer, pain is generally followed by vomiting; but I have notes of two cases in which operation established the diagnosis and the pain was of the most distressing kind, yet in which vomiting was a rare occurrence. Vomiting is useful only when present in a symptom-complex. It may occur in many gastric and general diseases. Last year was reported a cerebral tumor in a patient who, six months before, had been subjected to gastrojejunostomy. I am in the habit of placing this symptom last in the list for investigation.

Chronic atonic *dilatation* has no significance and must be disproven; pyloric spasm never occurs in these cases. Only when dilatation is accompanied by food stasis need it be considered, and even then the significance of these two symptoms must depend upon stomach analysis.

Stomach analysis, both microscopical and chemical, is our greatest aid in differentiation; but in order to be of value, it must be made with care and accuracy. The chemical analysis must be both qualitative and quantitative. It must be made by an expert, as in many cases his findings must be taken as final in deciding for or against operation.

Our routine is as follows: (1) Distention of the stomach to determine its position and mobility. (2) Withdrawal of contents of stomach 8 hours after ordinary meal to determine food stasis. (3) Analysis of the stomach-contents after test meal. (4) Misroscopic examination of contents of the fasting stomach. (5) Microscopic and chemical analysis of feces.

It has been stated that discretion is necessary in this class of cases in the use both of the stomach-tube and of distention. We have never had an accident and feel quite free to use either in any case where it seems necessary to establish a diagnosis. Perforation from any cause is the exception and not the rule. In 20 years of abdominal work I have seen only six cases. Dr. Edward J. Ill of Newark, who has had an extensive work for years, has seen only one. Ellsworth Eliot, Jr., of New York reported but seven at the New Jersey State Medical Society Meeting in 1908, and Monahan reports 27 cases.

We may now ask ourselves what causes the symptoms of pyloric stenosis. It may be a spasm of the pyloric outlet or an organic stenosis.

Spasm of the pyloric outlet.—Our present knowledge of stomach digestion seems to indicate that the cardiac end of the stomach acts as a pouch or retainer of food, while the pyloric end, which is possessed of great muscular power, acts as the mixer or churn; and that the pylorus remains closed during digestion, and only opens occasionally to allow a certain amount of acid (*chyme*) to pass into the duodenum. Cannon states that this action depends upon a proper acid mixture, and that when the acid stomach-contents are neutral, the valve-like aperture remains closed. This explanation coincides with our experience in cases of carcinoma and chronic pancreatitis, in which, at the time of operation, the size of the pyloric aperture does not account for the great food stasis.

The following case illustrates pyloric spasm due to a chronic obliterating appendicitis. In April, 1906, I was asked to see the wife of a New York physician who had been ill for several months. Her symptoms were those of marked pyloric stenosis, viz., vomiting and pain on ingestion of food. While her stomach was empty she was moderately comfortable, but as soon as food of any kind was taken, her agony was intense until relieved by vomiting. There had been periods, varying from a few hours to a couple of days, when the symptoms were ameliorated, and then, from some cause unknown to the patient, another attack would ensue and last several weeks. Her emaciation was most marked; she had lost 35 pounds and now weighed less than 100 pounds. Her skin was sallow and had lost its tone; the bowels were constipated. Nothing was found in a very thorough physical examination which would help in diagnosis, and there was no localized tenderness over the gall-bladder, stomach, or appendix. Gastric analysis showed a marked hyperchlorhydria. After studying the case carefully, I advised an exploratory celiotomy. At operation the stomach, pylorus, duodenum, and gall-bladder were found normal; but the appendix was undergoing a fibroid change (appendix obliterans). Appendectomy was performed, and at once the

whole picture was changed; the patient gained 35 pounds in six months, could eat anything, and there has never been a recurrence of the pyloric spasm.

A merchant 56 years old had for a number of years been treated for chronic dyspepsia—hyperchlorhydria. His physician stated that he had always been relieved by alkalines until a year ago, when mineral acid acted best. (I think the above statement an important one as an aid in diagnosis.) Twenty-four hours before I saw him, he was attacked at night, after a hearty meal, by severe general abdominal pain, followed by frequent vomiting, which continued and was not relieved by half a grain of morphine given hypodermically. When I saw him, his temperature was normal; at frequent intervals he was vomiting a dark fluid containing mucus, bile, and microscopic amounts of blood. The stomach was apparently dilated, though the degree was undetermined, since the whole abdomen was distended. There was a mild jaundice. There had been no stool for 24 hours, but he had passed a small amount of gas per rectum. He looked to be a very sick man. There was no bulging at the hernial openings; both obturator foramina were free; rectal examination was negative; leucocytes 8,000, polymorphocytes 72 per cent.; urine negative; no distinct tenderness except over the pancreas, and this only moderate; esthesiometer 10. His stomach was washed out and a large quantity of dark fluid secured, which was faintly acid and contained bile but no shreds. The stomach was washed out at four-hour intervals for three days, when the pyloric spasm subsided and food passed as usual. This man had possibly had for years a chronic duodenal ulcer, which had healed with some contraction of tissue and adhesions producing a pancreatitis (this latter condition was proved later by examination of the stools and the urine.) After unusual indulgence in food, his chronic pancreatitis became acute, producing spasm of the pylorus. He is now quite well. Formerly we were in the habit of looking upon these cases as due to intestinal paresis, now we differentiate.

Some years ago I was asked to operate upon a gentleman who had a typical picture of pyloric stenosis. On opening the abdomen, I found a large dilated stomach with pylorus admitting two fingers (certainly no stenosis). I felt chagrined at my mistaken diagnosis and closed the abdomen without doing anything. My chagrin must have been mild, however, to that of a metropolitan brother-surgeon, who, six months later, laughed at my timidity. He opened the abdomen and did a posterior gastrojejunostomy. The patient lived long enough to haunt him, and beg him to close the stoma, as his last condition was worse than the first; his pyloric spasm was made worse instead of better. I saw this case before I knew much about spasm due to pancreatitis, but think this was such a case.

It has been pretty conclusively proven by Kelling that unless there is a true organic stenosis, no food will enter the jejunum through the stoma; but it is washed time and again against the spasmodically contracted pylorus.

Just what part diseases of the pancreas play in this most interesting condition we are not in position at this time to say, but cases have been reported by Mayo Robson which, when analysed, would seem to indicate that in the future we shall look upon pyloric spasm as a symptom of pancreatitis. Our present knowledge of pancreatitis is most vague, and the reason is easy to explain. This organ is situated deep in the abdomen behind the colon and duodenum, and is frequently covered by the stomach, making palpation impossible. Its diseases are either alarmingly acute—acute suppurative pancreatitis, or very chronic—chronic interstitial pancreatitis. Until quite recently no attention has been given to its pathology, and it is now receiving only its merited attention. I shall speak later of the part played by this organ in organic stenosis.

Organic duodenal stenosis may be caused by cancer, duodenal ulcer, benign tumors, pancreatitis, gallstones, and adhesive inflammation starting in the gall-bladder or ducts.

The question: Is cancer of the stomach a curable disease? may be answered as we must answer the question in regard to cancer in other regions of the body—yes, by early operation. Rodman's operation for the removal of the pylorus is a scientific and eminently successful operation when undertaken before glandular involvement, and when the tumor mass may be raised with the pylorus. On the other hand, gastroenterostomy for the relief of pyloric cancer has proven a failure, and this in the hands of the best operators. There is an immediate mortality of 25 per cent.; Mikulicz gives 25 per cent., Kroenlein 24.2 per cent. The prolongation of life after the operation, as compared with cases not operated on, is about three months (Mikulicz, Kroenlein, Dawson, and others). Patients with cancer of the stomach, as proven by operation, do not die from stenosis as a rule, but from the asthenia and toxemia due to the disease. Dawson of Guy's Hospital made a critical analysis of eight patients who had a gastroenterostomy performed for inoperable cancer of the stomach. In seven of these the duration of life was between six weeks and six months, and in all the quality of life was bad; all symptoms were unrelieved. In one, the patient gained two stone and in every way was better, but upon inquiry this was found to be a pylorectomy with gastroenterostomy (Rodman). When cancer of the stomach is inoperable and there is no doubt in my mind about the nature of the growth, I am not in the habit of doing a gastroenterostomy. While this latter opinion was gaining ground with others, I had become convinced that the immediate risk did not compensate for the small benefit derived.

The above showing should put physicians on their guard for the early recognition of cancer of the stomach. Remember that in ulcer the total acidity is high, 0.2-0.3 per cent. Most of the acidity is due to active hydrochloric acid, and free hydrochloric acid is present in large amounts; whereas in cancer, the total acidity is low, free hydrochloric acid is generally absent, and the combined form is present in small amounts. Physicians should also recognize that from 66 to 80 per cent. of all cancers of the stomach are implantations of carcinoma upon a chronic ulcer. Early cancer of the stomach is difficult of diagnosis and cure; whereas ulcer is comparatively easy both to diagnose and to cure.

True, or organic, duodenal stenosis may be due to a disease of the pancreas, as reported by Galladet, Monahan, and Mayo Robson. Robson states that the intimate relation of the head of the pancreas to the duodenum may lead to its invasion by diseases of the gland. He says: "I have seen this on several occasions, or the converse invasion of the pancreas from the duodenum," and, further, "I recently observed a case of this kind, in which the first effect of

the disease was to produce a stricture of the duodenum, and the next effect was a glycosuria which proved fatal." In the *Annals of Surgery* for August, 1899, Galladet reports a cancer of the head of the pancreas which totally obliterated the lumen of the duodenum. When the head of the pancreas is especially thick, it overlaps the sides of the second part of the duodenum, and may embrace one-third of its circumference; in rare cases it may surround the bowel. Should the pancreas be enlarged in such a case from any cause, such as catarrh of its ducts or interstitial pancreatitis, it would produce a constriction. Six such cases were reported by Mayo Robson, and in all there were symptoms of pyloric stenosis.

Chronic duodenal ulcer furnishes the greatest number of duodenal stenoses, and these, together with the stenoses due to adhesions, furnish us our most brilliant results. I know no more satisfactory operation in surgery than a gastroenterostomy or a Finney operation upon a patient who for years has been in pain and has suffered slow starvation. The effect is immediate; the sallow face clears, the subcutaneous fat reappears, and the patient is at once restored to health and usefulness. It is not uncommon for these patients to gain 30 to 50 pounds in six months. Monahan's latest statistics on the late results of operation (*British Medical Journal*, May 9, 1908) are as follows: Number of cases, 205; cured, 148; relieved, 5; doubtful, 9; not reported, 12; not relieved by operation, 12; died as result of operation, 2; died from cancer, 7; died from other causes, 8.

THE SYMPTOMATOLOGY OF TUBERCULOSIS OF THE LARYNX.

By GEORGE FETTEROLF, A.B., M.D.,

PHILADELPHIA, PA.

LARYNGOLOGIST TO THE HENRY PHIPPS INSTITUTE, THE WHITE HAVEN SANATORIUM, ST. VINCENT'S HOME AND THE PHOENIXVILLE HOSPITAL; DEMONSTRATOR OF ANATOMY, UNIVERSITY OF PENNSYLVANIA; FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

A GREAT step forward in diagnosis and treatment would be taken if a routine and comprehending examination of the larynx were to be made in every case of pulmonary tuberculosis. Unfortunately, the amount of patient effort, experience, and skill required to see and properly interpret the picture presented is such as to make a procedure satisfactory in the hands of comparatively few internists. Much has been said and written regarding the rôle and importance of the tonsils in tuberculosis, much that is of practical significance, and much that must always remain in the realm of pure theory. One reason for this is the comparative ease with which at least a superficial examination of the tonsils can be made. It is unfortunate that the difficulties of technique in the way of a laryngoscopic examination have prevented there being devoted to the larynx that general attention which the importance of the subject demands. As well ignore the stomach in the diagnosis and treatment of intestinal disease, or the urethra in affections of the bladder.

A case in point was seen within the last week. This patient was sent to me for a diagnosis of his laryngeal condition, with a history of hoarseness commencing eight months ago and gradually getting worse until finally there had supervened complete aphonia. Along with this there had been a slight loss of weight and a certain amount of lassitude. His physician reported to me that examination of his chest was negative, no bacilli could be found in his sputum, and Calmette's ophthalmic test was negative. With these data there was presumptive absence of tuberculosis and yet examination of the larynx revealed advanced tuberculosis of that organ, with extensive infiltration of the epiglottis and arytenoids and destruction of the vocal cords.

Should the invariable examination of the larynx become an accomplished fact much suffering would be avoided and many lives saved. This standard being at present unattainable, there are certain danger signals which should be inquired for and noted by the clinician, the significance of which should be early determined by one skilled in laryngoscopic examination. While there are undoubtedly some cases of laryngeal tubercle in which there is nothing to attract the attention of the attending physician, in the very large majority there exist signs pointing toward involvement of the voice-box. All that can be diagnosed without inspection is that there are probably present some tuberculous implantation and activity, the form, degree, situation, probable course, importance, and curability being determinable only by a view of the interior of the larynx. But if by inquiring into the symptoms an appreciation of the importance of laryngeal examination and treatment can be ascertained, not a little will have been gained.

Changes in the Voice.—These are positive indications of there being *something* wrong with the larynx and demand imperatively that the situation be cleared up. These vocal alterations may be tuberculous or nontuberculous in causation and may vary from slight transient huskiness to complete aphonia. The only deduction that can be drawn is that there is involvement of the voice-producing mechanism, the exact character, form, size, and situation of the lesion being determinable only by inspection of the interior of the larynx.

A symptom I have noted in a few cases is, during conversation, a slight rotation and twisting of the head, toward the position found in torticollis. When this has been present I have usually found a cicatrized and arrested tuberculous lesion of the voice-producing apparatus. It can be explained on the basis that the scars of the healed tubercles so pull upon and distort the intrinsic laryngeal muscles and interfere with their proper action that unconsciously the patient tries to aid in overcoming this interference by slightly changing the position of the larynx.

In this connection it should not be forgotten that while the patient is tuberculous the lesion in the larynx may be of an entirely different character, *e.g.* syphilitic, hysterical, a part of a general asthenia, or the result of mechanical interference with the nervous mechanism of the larynx, especially the inferior and external laryngeal nerves.

Cough.—As there may be pulmonary tuberculosis without cough, so may there be similar disease of the larynx without any resultant cough. As is the case with other symptoms, this is dependent upon the form and situation of the lesion. After inspection of the interior of an irritated larynx it is always difficult to determine to what extent the irritation is secondary to the cough or the cough secondary to the local disease. This can be determined only by a critical correlation of the data obtained by examination of the chest and throat, combined with an appreciation of the "habit" of the patient.

As a practical working basis it can be assumed that if the cough is harsh, "throaty" in quality, and unproductive or out of proportion to the amount of sputum, there is present more or less laryngeal irritation at whose door can be laid some of the responsibility. And, if there be absence of or but slight alteration in the pitch and quality of the voice, in all probability there will be found some involvement of the interarytenoid region.

Should there be present large infiltrations of the arytenoids the patient will have a characteristic, tubular, indescribable quality to the voice which is almost pathognomonic. After it has been heard a certain number of times it will readily be appreciated and interpreted. It is in all probability due to the alteration of the shape of the glottis by impingement on its lumen of the enlarged arytenoid cartilages.

Sputum.—Not much that is significant can be gathered from study of the sputum. Microscopical examination will afford no information whatever, for if bacilli are present the natural and reasonable assumption will be that they are derived from open pulmonary tubercles.

There is, however, one condition appertaining to the sputum, which should point at once to a searching examination of the larynx. The following history is not infrequently presented: The patient awakens with a feeling of fulness and dryness in the throat, associated with huskiness or some degree of aphonia. On arising coughing begins, frequently associated with retching or even vomiting, and continues until there is ejected a discoidal mass of inspissated mucopus, dark, hard, and dry on one side, and yellow, green, sometimes blood-flecked, and moist on the other. But before attaching special importance to a mass of this kind one should be careful to elicit clearly the fact that it is coughed up from below and not "hawked" down from the nasopharynx, whence such crusts so frequently come.

These accumulations form in the interarytenoid region and are due usually either to a desquamative process or to a hyperplasia. Occasionally they may be cast off from erosions or ulcers situated elsewhere in the larynx. The rationale of their presence is that the natural upward current of the pulmonary secretions and entangled inspired particles is interrupted and during sleep there is slowly dammed up a quantity of gummy material, which during the somnolent quiescence of the larynx thickens, dries, and becomes adherent to the subjacent tissue. In the morning its presence is appreciated and Nature's method of removal, coughing, is instituted, phonation being meanwhile completely or partially prevented by the mechanical interference of the crust with the vocal apparatus. The presence or absence of the blood specks is dependent upon the depth of the underlying erosion or the persistence with which the crust adheres. Ejection results in either immediate or slightly delayed return of the voice.

A possible source of error is that similar but usually smaller accumulations are the result sometimes of tracheal erosions, but in such an event there would be no interference with voice production.

Blood.—The presence of blood in the sputum can be but rarely attributed to the larynx. Out of many hundreds of cases of laryngeal tuberculosis examined in but one have I seen bleeding from the larynx. This case was a young woman with a huge cicatrized left arytenoid, and from the left laryngeal ventricle was trickling a slight but steady stream of blood, which tended to accumulate upon the anterior third of the vocal cords. My experience has led me to believe that in tuberculosis hemoptysis traceable to the larynx is so rare as to be practically a negligible factor.

Pain.—This is the most serious symptom of all and should always be a matter of the deepest concern. It is worthy of note that while as a rule pulmonary disease is almost painless, even in its worst phases, tuberculosis of the larynx presents at times one of the most pitiable pictures which a medical man has to face. It is probably for this reason that the laity look upon "throat consumption" as being such a terrible disease.

If the pain is transient and associated with other symptoms of acute inflammation it may be due to an acute process which will undergo prompt resolution, leaving no untoward sequelæ. If it partakes of the nature of a dull, heavy ache and is associated with the sensation of a "lump in the throat," this sensation being increased during swallowing, there is probably present some infiltration of the arytenoid cartilages, or early disease of the epiglottis. If the pain is of a more severe type and especially if agonizing during swallowing, there is likely to be found a general infiltration or marked ulceration of the supralingual portion of the epiglottis. Should the pain be noticeable only during the ingestion of acid fruits and highly seasoned food it can be assumed that there is present an ulcerative condition of that part of the larynx with which the ingesta come in contact during deglutition. This area comprises the epiglottis above the cushion, the posterolateral aspect of the arytenoepiglottic folds and the pharyngeal surface of the arytenoids.

Pain radiating toward the ear usually indicates involvement of the same side of the larynx. If it occurs when the larynx is at rest it generally indicates a lesion of the ventricular band or the arytenoid cartilage, and of the latter usually a late form. If it occurs during deglutition, advanced disease of the epiglottis is probably present, in addition to a possible involvement of the arytenoid or the ventricular band.

Odynphagia.—This is a symptom of decided importance and varies in degree from a mere evanescent discomfort to a degree of suffering so agonizing as to practically prevent the taking of food. When this is present there can usually be found involvement of some portion of the oblique periphery of the larynx, which includes the epiglottis, the arytenoepiglottic folds, the arytenoid cartilages, and the interarytenoid region. The most severe forms are usually dependent upon disease of the epiglottis, which may be either infiltrative or ulcerative in character.

Dysphagia.—This is rarely present unless associated with odynphagia. It is infrequent that one finds a swelling of sufficient size to cause difficulty in swallowing without there being some degree of pain. In other words, in laryngeal tuberculosis in which the patient experiences trouble in deglutition, it is usually due to the pain and rarely to purely mechanical obstruction.

Dyspnea.—This symptom may occur early or late and may be of so slight degree as to create the impression in the mind of the internist of being pulmonary or cardiac in origin. It may be due to an acute process, to a true hyperplasia or infiltration or to a rapidly or slowly advancing edema. In one

case of mine in which tracheotomy finally had to be done, there was noticed a gradual failure of motility at the cricoarytenoid joint and a slow approximation of the vocal cords. A transient form is often seen in which either moist or dried sputum catches in the larynx and causes terrifying interference with the passage of air.

In connection with the above summary of symptoms there are one or two points that should be mentioned. One is that the enumerated symptoms have been considered only in their relation to the larynx, to the exclusion of possible diseased conditions in other parts of the upper respiratory tract, and in analyzing them the tonsils, pharynx, uvula, etc., should receive proper consideration. Another point is that these symptoms are being elicited from the patient and not from the disease, and therefore the nature of the patient, his personal equation, and all other concomitant conditions should enter into the calculation before attaching the proper value to the information that may be received by questions as suggested in this article.

330 South Sixteenth Street.

Urobilinuria not a Sign of Hepatic Insufficiency.—A. Gilbert and M. Herscher tell us that all the clinical facts show that the kidney rather than the liver has to do with the production of cholemia. The kidney acts as a chemical reducer whose power can be increased or diminished. Urobilin is not the pigment of a diseased liver but is derived from normal bile pigments, produced by reduction in the kidney. Urobilinuria is not a sign of liver insufficiency, but an indication of cholemia which allows us to judge of the kidney condition. The authors give illustrative cases in three groups: urobilinuria with normal liver; absence of urobilinuria with hepatic insufficiency; and absence of urobilinuria when there is hepatic insufficiency, followed by urobilinuria when the liver begins to function normally.—*La Presse Médicale.*

Rapid Artificial Dilatation by Bossi's Method.—Joaquin Cortiguera considers Bossi's dilater the best instrument for dilatation of the cervix when rapidity is desired. The various other methods are much slower and expose the patient to the dangers of infection for a longer period of time. The various instruments used are more apt to become septic while in use. To apply the different forms of rubber bags a preliminary dilatation is necessitated before they can be introduced. Deep incisions require suture, Bossi's dilator is easily made aseptic and easily applied. There is no need of serious tears or hemorrhage if it is applied slowly, from three-quarters to one and one-half hours being used in completing labor. This method should be used only when there is serious danger to the mother. Dilatation should reach a little more than the diameter of the head, since some contraction takes place after the withdrawal of the instrument. It is indicated at all stages of pregnancy when it becomes necessary to terminate pregnancy for the sake of mother or child. It is contraindicated whenever the pelvis is too small to permit of natural delivery. It is indicated when the fetus is abnormally large, as when labor is delayed more than nine months; when the shoulders are very large; when the internal os is contracted; in eclampsia; and in placenta normally implanted, but prematurely separated. In placenta previa it is doubtful if it is as efficacious as version.—*Journal de Médecine de Paris.*

Contribution to the Study of Oppenheim's Disease.—Simonini describes a case of Oppenheim's disease observed by himself. This disease consists of a flaccid paralysis involving most of the muscles of the body, more markedly those of the arms than of the legs, accompanied by absence of reflexes and of contractures. The muscles of the neck and back are affected so that the patient is unable to sit erect or hold up the head. Sensation is perfect. The affection is congenital. There is no atrophy of the muscles and those of the face are not affected. Electric excitability varies and may be diminished. Intellect is not affected, nor the special senses. The affection seems to be a miatonia rather than a paralysis. There seems to be no central nervous lesion but rather a non-development of the muscular system. The affection is susceptible of amelioration by treatment.—*Rivista di Clinica Pediatrica.*

Aphasia and Broca's Convolution.—A recent editorial notice in the *British Medical Journal* refers to Marie's observations of the left cerebral hemisphere of a case of complete motor aphasia which seemed to show that Broca's convolution was unaffected. This surmise was verified by numerous sections which revealed an area of softening in Wernicke's zone in the temporoparietal region. At the same time he showed the brain of a right-handed patient who during life had been affected with word-blindness, word-deafness, agraphia, and jargonaphasia, without anarthria (inability to articulate words), which is the complex of symptoms known as Wernicke's aphasia. There were two foci of softening in the left hemisphere; one of these involved a large part of the foot area, and orbital part of the third, and the posterior third of the second, left frontal convolutions. The other involved the upper half of the posterior third of the first temporal convolution, and of the middle part of the inferior parietal lobule sparing the angular gyrus. Horizontal sections showed that the frontal lesion was very deep, and that besides the injury to the third frontal convolution the destruction had involved the anterior portion of the island of Reil; the posterior two-thirds of the island of Reil were intact, as were also the external capsule, the internal capsule, the central gray ganglia, and the deep temporal. The temporoparietal focus of softening although extensive was superficial, and did not penetrate deeply into Wernicke's zone. These lesions explain the symptoms quite satisfactorily on Professor Marie's theory, as Wernicke's aphasia is due to softening of the temporoparietal gray matter; the integrity of the temporoparietal isthmus and of the lenticular region explain the absence of anarthria, while, in spite of the extensive and deep lesion of the third frontal convolution, there was no motor aphasia, which is inconsistent with the generally accepted doctrine.

Pathogenesis of Nervous Complications in Pertussis.—Durando Durante finds that nervous complications of pertussis are not rare. He has made a study of the cause of the occurrence of these symptoms. The clinical picture is very various and differs in intensity and extent. The commonest symptom is convulsions. There are various forms of paralysis, bulbar, spinal, and peripheral, polyneuritis, and troubles of the special senses. The pathogenesis is not well defined. The rapid onset, short duration, and recovery indicate that there is no permanent lesion. They may result from hemorrhage, and changes in the circulation due to the violence of the cough, and increase of blood pressure. Another explanation is that they are due to carbonic acid poisoning from asphyxia. Predisposing causes are weakness, loss of sleep, and inability to retain food. The specific toxic element of the disease is an important factor. The author has made a study of the expectoration in these infants. He finds that there is marked increase in virulence of sputum from such cases.—*La Pediatria.*

A Safe Method of Opening the Abdomen.—The Vienna correspondent of the *Lancet* calls attention to Lihotzky's method of opening the abdomen—the supra-symphyseal transverse section of the fasciæ. The incision is from three to four inches long, slightly curved, and extending transversely over the pubes, dividing the skin, subcutaneous tissue, and fasciæ. The latter are then detached from their base upward and downward so that the recti and pyramidales muscles are free. The recti muscles are then divided in a longitudinal direction so that they are held only by a thin layer of connective tissue and the transverse fascia and the peritoneum are subsequently incised. This method gives a very ample access to the abdominal and pelvic organs. Tumors reaching up to the umbilicus can be easily removed through the opening. All operations on the uterine adnexa as well as the total extirpation by Wertheim's method and the operative treatment of extrauterine pregnancy can be easily performed. The closure of the wound is effected in the following manner. The peritoneum and the recti muscles are sutured in the longitudinal direction and the fasciæ and skin in the transverse direction. The sutured wound is covered with gauze, held down by two strips of adhesive plaster. After eight days the sutures in the skin are removed, after which the patient may be out of bed without any abdominal belt. The cosmetic defect of the scar is soon concealed by the hair growing over it, especially if the incision is not very large, while the transverse scar is not liable to become stretched with formation of ventral hernia. This functional superiority of the horizontal incision over the vertical one has been proved by many hundreds of cases in Germany and also in Austria. The method is also available for a bilateral Bassini operation if the angle of the incision is drawn well to the side by means of a blunt hook.—*The Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, January 23, 1909.

MODERN CONCEPTIONS OF TYPHOID FEVER.

VIEWS as to the origin of various diseases are changing constantly, or rather, it should be said, developing. Knowledge in regard to their causation is ever on the increase, and the more that is learned concerning them makes those whose life work is research realize how much more remains to be discovered. The past few years have been especially fertile of valuable work, both in true scientific research and in placing the discoveries already made on a proper footing. At the present day, for example, to isolate and make known a germ which has been invariably found in those suffering from a certain disease, does not always warrant the discoverer in the absence of other evidence in stating with confidence that this germ is the sole causative agent. For instance, but a few years ago it was believed that the *Bacillus typhosus* of Eberth alone was the causal agent of typhoid fever, but such is not the general belief at the present time. Major I. C. B. Statham, writing on the complex nature of typhoid etiology in the *Journal of the British Royal Army Medical Corps,* for October, 1908, says that the knowledge of recent years has forced us to realize that there are quite a number of allied but distinct species of bacteria, any one of which is capable of originating typhoidal disease, that in fact the etiology of this condition is as complex as its symptomatology. Again he says that we now also know that this group of bacteria, while at one time originating a disease with all the clinical symptoms of typhoid fever, may at another time cause pathological conditions utterly unlike it. Typhoid fever is, in fact, a group disease produced by a group of organisms. Major Statham gives a list of five subgroups of bacteria capable of originating disease in man indistinguishable from typhoid fever. These are: (1) *Bacillus fecalis alcaligenes;* (2) *Bacillus typhosus;* (3) *Bacillus paratyphosus A;* (4) *Bacillus paratyphosus B;* (5) *Bacillus coli.*

In connection with Major Statham's paper, Mr. Leonard S. Dudgeon, in the course of the Horace Dobell lecture, delivered before the Royal College of Physicians of London on November 12, 1908, referred to the persistence of the pathogenic bacteria causing typhoid fever, and he would not limit the term "typhoid carrier" to the carrier of the typhoid bacillus, but to one who harbors any of the organisms mentioned by Major Statham. The persistence of the germs of typhoid fever for longer or shorter periods is manifestly of the utmost importance, and this fact has been known for only a comparatively short time. But that the feces or urine of patients who have recovered from typhoid fever may be infective and a wide source of danger for months or even years is now a matter of common knowledge. It is stated that from about 3 to 4 per cent. of typhoid convalescents become chronic carriers and of those who have been associated with typhoid cases a small proportion may excrete the bacillus temporarily; and moreover it has been shown that those who never had any illness which had been regarded as typhoid fever may have bacilli of the typhoid-paratyphoid group in their feces. Mr. Dudgeon in his lecture gave numerous instances of the persistence of germs causing typhoid fever amongst individuals who had either suffered from the disease or whose illness had not been diagnosed as such, or who had not suffered from typhoid fever or from any disease resembling it. In conclusion, he drew attention to the point that the latent persistence of the typhoid-paratyphoid group of organisms in the tissues is of considerable importance from whatever aspect the subject is considered. That organisms which are known to be capable of giving rise to serious epidemics may practically live as saprophytes in our tissues, with or without occasional periods of activity, or be discharged from our bodies and thus be the source of acute infection in a fresh host, must be regarded as a reason for reconsidering our views concerning these infections.

Many epidemics of typhoid fever have been mysterious in their origin and some impossible to trace. The persistence of the bacteria causing the disease in the bodies of those who have undergone an attack will explain to a large extent the origin of many untraceable epidemics. Probably of all the "typhoid carriers" those termed temporary or acute carriers, who excrete the typhoid bacilli for a short time only, are the most dangerous to the health of the community. It may be mentioned as an interesting fact that many writers on the subject have noticed the far greater frequency of typhoid carriers among women and also that in women biliary calculi are of very common occurrence.

THE INTERPRETATION OF BLOOD PRESSURE RECORDS.

THE estimation of blood pressure has assumed such importance in the practice of medicine that a sphygmomanometer now forms a part of the equipment of many physicians, and charts of blood pressure as affected by drugs and other treatment compose a part of the routine records in several hospitals of New York City and elsewhere. On the other hand, the essential meaning of the records thus obtained is not completely agreed upon. In the first place, the accuracy of the instruments used and their comparative uniformity has been widely questioned by experienced clinicians whose fingers often fail to appreciate greatly increased tension in the arteries which is shown to exist by the manometer reading. Then again the readings given by the machines have

been widely looked upon as depending only upon the pressure existing within the vessels, and but little if at all affected by the condition of the vessels themselves. It is this latter teaching that is seriously questioned by William Russel in his recent monograph on the subject (Arterial Hyperotonus, Sclerosis, and Blood Pressure," Edinburgh, 1908). According to him at least three elements enter into the production of the record that is usually spoken of as blood pressure. They are the soft tissues surrounding the artery, the arterial wall, and the pressure of the blood within it.

The first factor is practically negligible and has been so treated by all users or designers of blood pressure machines. The second factor, on the other hand, is of the utmost influence upon the production of the reading, a fact which Russel has demonstrated by an ingenious apparatus in which tubes of different thickness were used to represent blood vessels. The pressure within these tubes was carefully kept at a uniform point, yet it took widely different external pressures to obliterate their lumina. The conditions of these experiments closely approached the circumstances existing in the blood-vessels of the animal, so far, of course, as dead material could imitate the living vessels; the conclusion drawn from them by Williams is that not a small part of the record usually designated as blood pressure is due to the thickening of the arteries, whether this is caused by a permanent change in their substance or is due simply to the temporary contraction of their muscular walls. The best clinical evidence of this he finds in the enormously high reading obtained in some chronic cases. If these readings were to be taken to indicate the existence of such blood pressure in the arteries the conclusion would be unavoidable that the vigor of the heart could rise to something like 200 per cent. above the normal in a disease like chronic interstitial nephritis. The assumption of Williams that the tightening of the arteries is responsible for these high readings certainly seems much more probable.

At the same time, though the interpretation of the readings obtained with the sphygmomanometer must be changed if the conclusions made by Dr. Russel are to be accepted, the value of the instruments is not at all diminished. The only thing to do is to devote careful study to the separate elements responsible for the manometric reading; the effect of illness, medication, or any other factors upon the different elements may then be learned and the phenomena of circulation both in health and in disease be better understood. The vascular phase of disease in contradistinction to the cardiac element has recently attracted much earnest attention, and Dr. Williams' contribution is an extremely valuable addition to that subject.

BOVINE TUBERCULOSIS.

The effect of milk and meat obtained from cattle suffering from tuberculosis is assuredly one of the most burning questions of the day, from the point of view both of the general public and of the medical profession. However, it is now more or less a matter of agreement among the majority of medical men that tuberculosis can be transmitted and spread by infected milk. As for the danger to be feared from the consumption of meat from a tuberculous animal, opinions are far less decided, and perhaps the view generally held is that infected meat is not often, if ever, a means of transmitting tuberculosis. In a few words, it may be stated that milk from tuberculous cows may be looked upon as a grave menace to the health of the community, but that sufficient is not yet known concerning the danger to be apprehended from tuberculous meat to warrant definite statements being made. The whole subject of bovine tuberculosis affects this country more probably than it affects any other country of the world, owing to the enormous business done in the rearing of cattle. Consequently, at the recent international congress on tuberculosis, held in Washington, great prominence was given to this question. It is known that, or rather it is a matter regarding which there is but little doubt, that the tuberculous cow is a source of much danger to the community. The object now is how to minimize this danger as far as is possible. It may not be feasible wholly to eradicate tuberculosis from dairy herds, at any rate not for a very considerable period of time, but it is feasible to place things on a more satisfactory footing than they stand at present in this respect. A great difficulty in the way of successfully solving this problem lies in the fact that it is not known or nearly known how many cows in this country are tuberculous. Estimates as to the prevalence of tuberculosis among dairy cows vary very widely. By some authorities it is given at 10 per cent., and others put it at 90 per cent. Doubtless both estimates are erroneous, but it is certain that very large numbers of tuberculous cows exist in all parts of the world. Cows may seem to be in splendid condition and yet may suffer from tuberculosis. All those that react to the tuberculin test have tuberculosis, however slightly, and the question is what is to be done with them.

It used to be an article of belief that the only cows which were distinctly dangerous were those which had tuberculosis of the udders, but it is thought now that this limitation is not sufficiently stringent. Dr. E. C. Schroeder, for instance, points out in Bulletin 118, issued by the United States Bureau of Animal Industry, that many tuberculous animals expel tubercle bacilli in the feces and in consequence are liable to contaminate the milk during the process of milking. It would not be practical or practicable to destroy all animals that showed a reaction to the tuberculin test. Further, it must be borne in mind that cattle that have been tested frequenly fail to react, although they may have become tuberculous in the meantime. Dishonest methods also may render testing abortive, and mistakes are not infrequently made even when great care is taken. In certain cases the use of tuberculin may have assisted to spread the disease, as cattle thus shown to be tuberculous, as a rule are sold at once and may carry the disease to other herds into which they are admitted.

The entire matter simply bristles with difficulties

and must be approached in a cautious manner. Dr. J. G. Rutherford of Canada, speaking on the subject at the congress at Washington, thought that some sort of legal control was absolutely necessary and that all milk from cows that reacted to the tuberculin test should be pasteurized. He was also of the opinion that one or more clinical cases occurring in a herd should suffice to justify Governmental interference, together with the compulsory preparation of a report. On one point probably all who desire to check the spread of tuberculosis by means of infected milk will be agreed, namely, that all cows which have tuberculosis of the udder should be destroyed. Segregation of diseased animals would be another step in the right direction. After all, the most obvious method of eradicating tuberculosis from dairy herds and from cattle generally is to keep the animals under good sanitary conditions. As long as cattle and cows are massed together in ill-ventilated, unhygienic sheds so long will tuberculosis flourish among them. Open air treatment is as much indicated for tuberculous cattle as for tuberculous human beings, and if cattle and men were reared in a hardy way there would be less of the disease among both.

The tuberculin test is valuable, and clinical diagnosis is valuable, and methods of dealing with the disease when discovered are absolutely necessary if its dissemination by the agency of milk is to be stopped. But preventive measures are even more important. The question of bovine tuberculosis in all its bearings needs practical discussion. The fringe of the subject has been as yet only touched. It is a healthy sign that in almost all civilized countries the matter is receiving close attention.

Glycosuria in Pregnancy and the Puerperium.

The presence of sugar in the urine of pregnant women has been so variously interpreted by physicians that an authoritative statement of conclusions warranted by a careful study of this question would be very welcome. Such a study founded upon personal experience and a review of the literature of the subject is presented by Dr. J. Whitridge Williams in the *American Journal of the Medical Sciences* for January, 1909. He has grouped all the cases under the headings of lactosuria, transient glycosuria, alimentary glycosuria, recurrent glycosuria, and diabetes. So far as the first is concerned, the presence of moderate amounts of lactose in the urine at the beginning of mammary engorgement in early pregnancy and in the beginning of the puerperium is to be looked upon as a nautral physiological phenomenon. The slight difficulty of identifying this variety of sugar should not be sufficient cause for neglecting such identification and making a prognosis upon the mere presence of sugar. The usual test for sugar, the reduction of copper salt solutions such as Fehling's, should not be used alone in the examination of the urine of women during these periods, for the prognosis depends almost wholly upon the identification of the variety of sugar present. Neither transient nor alimentary glycosuria has been satisfactorily explained, but the prognosis of these conditions is not at all a serious one. The appearance of these forms of sugar excretion may simply show some abnormality in the carbohydrate metabolism that is not productive of any serious effects upon the organism, and this is partly true even of recurrent glycosuria. Real diabetes, that is, the excretion of glucose in the urine for long periods of time, the amount of the fluid being markedly increased, and constitutional effects being present, is quite another matter and forms a very serious complication of pregnancy. Even here, however, the usual gloomy views of physicians are not borne out by the study of Williams. His conclusions are that many patients do perfectly well in spite of this condition, though a small proportion run the danger of dying in coma or collapse at the end of pregnancy or at the beginning of the puerperium. If the amount of sugar is large and cannot be markedly diminished by dietetic and medicinal treatment the induction of abortion is indicated even though no serious symptoms have yet appeared. On the other hand the appearance of small amounts of sugar may be explained by the existence of transient or alimentary glycosuria, and the diagnosis, therefore, should be deferred to the end of the puerperium when a careful study of the sugar excretion should be made. The main point, Williams maintains, is the necessity of examining the urine of pregnant and puerperal women at much more frequent intervals than usual, if sugar has been once demonstrated. Any measure taken will not of course cure the underlying disease, if the diabetes exists, even though abortion is induced. Yet the mortality of mothers may be very much diminished by suitable dietetic and medicinal treatment in some cases and by more radical procedures in others.

The Toxic Effects of Physiological Salt Solution.

The beneficial effects of infusions of salt solution in many pathological conditions are so well known that there is little tendency to seek for any untoward manifestations that may accompany this procedure. That the introduction of this fluid is not at all an indifferent matter to the organism is shown, however, by the observations of Meyer and Rietschel, reported in the *Berliner klinische Wochenschrift* for December 14, 1908. These authors confirm the findings of Schaps, who showed that infants reacted with a distinct rise of temperature to the injections of even very small amounts of physiological salt solution; this rise of temperature was quite specific in character, appearing four to six hours after the injection and either dropping suddenly on the same day or continuing for a somewhat longer period of time. This phenomenon agrees very well with the facts observed by Jaques Loeb, who has shown the toxic effects of physiological salt solution upon the low forms of organized life. The addition of a minute amount of potassium or calcium chloride was, however, all that was necessary to overcome the harmful effects of the solutions of salt, the eggs of *Fundulus*, for instance, being capable of living in such a solution though they promptly died in a solution of salt alone that was quite isotonic with sea water. Meyer and Rietschel have applied the results of Loeb's researches in their own work and have likewise found that the addition of the salts of potassium and calcium to the solutions of sodium chloride led to the disappearance of the reaction in many infants and to the diminution of its intensity in all. It was possible, indeed, to produce a febrile reaction by the injection of plain salt solution, then

to inject the potassium or calcium fluid without any untoward manifestations, and again to cause the return of the febrile movement by a repeated administration of plain salt solution. Of course the adult human being is not nearly so sensitive to the subcutaneous injections of salt as the infant; yet the reaction produced in the case of the latter probably means that the adult organism is likewise not perfectly tolerant of the solution. The wide use of salt solutions for the purposes of subcutaneous and intravenous injections would make it advisable, therefore, if these experiments are confirmed, that the proper amount of calcium and potassium salt necessary to inhibit its toxic action should be added.

Surgery and Fulguration Combined in the Treatment of Cancer.

The first use of fulguration was by Keating-Hart, in 1907, the results of his treatment being presented by Pozzi to the Paris Academy of Medicine. It had been used in several inoperable cases of cancer, with such a measure of success that other surgeons were urged to make use of the method and report their results. An operation was done in these cases which in itself would not have been sufficient to prevent recurrence, such as curetting, or removal of the ulcerated surface, and after it a current of high frequency and high tension was applied to the operated surface. The results were relief of pain, amelioration of all symptoms, and a firm cicatrization of the operated surface. C. Juge, in the *Archives Provinciales de Chirurgie* for September, 1908, reports the use of this method in forty cases with excellent results. The immediate effect of the electrical treatment is a certain amount of destruction of tissue followed by a lessening of the tumor, called by the author *sideration*, and a firm cicatrization. Hemostasis is immediate, and relief of pain is almost immediate after the recovery from anesthesia. In cases in which the cancer is not cured its development is indefinitely retarded. The immediate effect is a reddening of the surface, and with a continued application a destruction of tissue, that is not cauterization. Another effect is the pouring out of a copious serous fluid. An eschar is formed, sloughs off, and is followed by granulation and cicatrization. The fibrosis that occurs at the site of the tumor radiates in all directions and contraction ensues. This method is especially applicable to inoperable cancers. It enables a good result to be obtained in cancer of the breast without cleaning out the entire axilla. In cancer of the cervix, which has or has not invaded the broad ligaments, excellent results are obtained, which, so far as can be judged at present, will be permanent. In some cases, Juge asserts, a cure has undoubtedly been obtained.

News of the Week.

Health of the Canal Zone.—During November, 1908, the death rate in the Canal Zone was 23.71, as compared to 28.86 in November, 1907. Among employees alone the decrease was 9.10 per thousand, the total number of deaths being forty, thirty-one of which were from natural causes and nine from violence. The number of cases of malaria admitted to the hospitals during November was considerably less than in October. There has been no case of yellow fever since May, 1906, and no bubonic plague since August, 1905, though both of these diseases have existed on the Atlantic and Pacific coasts within three days' sail.

Scarlet Fever Outbreak.—Eleven students in the agriculture course at Cornell University are ill with scarlet fever, and are confined in the contagious ward of the hospital. The rapid spread of the disease is giving considerable concern to the health authorities.

Diphtheria Epidemic.—An epidemic of diphtheria has broken out in the State village for epileptics at Spillman, N. J. The State Board of Health has taken charge of the situation, and physicians and nurses from outside the institution have been called in. Nearly 400 inmates have been treated with diphtheria antitoxin, and all suspects have been quarantined.

Increase in Tuberculosis.—In spite of the systematic work carried on for the past few years in combating tuberculosis, there were in New York State during November, 1908, 1,101 deaths from the disease, an increase of 31 over the same month of 1907, and six more than the average for the last five years. The number of deaths from pneumonia decreased from 838 in November, 1907, to 683, in November, 1908, the average number for the last five years being 1,119. There was a decrease also in the deaths from typhoid fever.

Street Car Accidents.—During the year 1908, according to the report of the Public Service Commission, 444 persons were killed by the steam, subway, surface, and elevated railway lines of New York City, and the total number of accidents was 56,481. Of this total number, the surface roads were responsible for 42,391; while the fatal accidents on the surface lines numbered 248, on the subway and elevated, 89, and on the steam railways within the city limits, 107.

A Conference on Dependent Children.—On February 2, at Albany, will be held the annual meeting of the State Charities Aid Association. This meeting will take the form of two conferences on the prevention of public dependence, not only of children but also of the blind, insane and the tuberculous; one in the afternoon at Centennial Hall, and one in the evening at the Assembly Chamber. Hon. Joseph H. Choate will preside, and Governor Hughes, Judge Ben. Lindsey of Denver, and others will speak. It has been authoritatively estimated that there are 30,000 dependent children in New York State who are maintained at an annual cost of $5,000,000. The placing of many of these children in private homes would be of so much advantage, not only to the children, but to the taxpayer, that it should arouse the interest of every citizen of the State and country.

Damages for Leaving Gauze in the Abdomen.—A judgment of $4,000 was recently entered against Dr. M. L. Harris of Chicago in the Federal Court in favor of a man of Bowling Green, Ohio. It is said that four years ago the man came to Chicago and entered the Policlinic Hospital as a charity patient, where Dr. Harris removed one of his kidneys. After the operation was performed the patient was attended by the regular staff of the hospital, and it is claimed that a large piece of gauze was left in the wound. The jury was instructed by Judge Landis to the effect that it made no difference whether or not Dr. Harris personally

made the mistake, that he was responsible for anything that happened to the patient, he having been the operating surgeon. A notice of appeal from this judgment has been entered.

The New Milk Law for Chicago, which requires the pasteurization of all milk and milk products other than those from cows which have passed the tuberculin test, became effective January 1, but it is thought it will require several months for its complete enforcement. In the meantime, the city health officials are adopting routine measures to procure pure milk.

The International Tuberculosis Exhibit, which had been opened to the public daily at the American Museum of Natural History since Monday, November 30, 1908, closed last Sunday night at 10 o'clock, after having been seen by 753,301 persons. The exhibit almost in its entirety will be taken to Philadelphia as soon as practicable and shown under the direction of that city's Department of Health.

"Health Month" for Negroes.—During the month of February practically every church, lodge, and society for colored people in Chicago will hold meetings to consider the subject of "Tuberculosis Among the Negroes: What Are We Going to Do About It?"

Clean Beds in Nebraska Hotels.—A bill has been introduced in the Nebraska Legislature providing that all hotels in that State shall be inspected annually, that all bedding therein must be aired and disinfected at least once every three months, that in every wash room a clean individual towel shall be furnished each guest. Another provision is that hotels shall provide each bed with pillow slips and under and top sheets of white cotton or linen, and all such pillow slips and sheets after being used by one guest must be washed before they are used by another guest.

A Public School for the Blind.—The New York Board of Education has authorized the city superintendent to make arrangements for starting a school for the blind in connection with the public schools. It will be the first of the kind in this city and will begin with four classes.

Dr. Francis J. Murray has been appointed to fill the position of police surgeon made vacant by the death of Dr. J. J. Quigley recently. Dr. Murray is a graduate of Yale and of the College of Physicians and Surgeons in New York.

Dr. Arthur William Meyer, at present professor of anatomy in the Northwestern University, has been called to the chair of human anatomy in the Leland Stanford University of California. It is expected that he will take up his new work in August, 1909.

Women's Medical College.—Plans have been filed with the Building Department for a solarium to be erected on the roof of the Women's Medical College at the northeast corner of Livingston Place and Fifteenth street, New York, overlooking Stuyvesant Park. It will be of iron and terra cotta, with a large skylight of wired glass, having a frontage of twenty-three feet and a depth of forty-five feet.

Gifts to Charities.—The will of the late Louis A. Heinsheimer, who was for some time treasurer of the United Hebrew Charities, provides for the bequest of one million dollars to certain Hebrew charitable institutions, provided that they form a corporation to administer the fund. Among the institutions named are Mt. Sinai Hospital, the Montefiore Home, the Hebrew Orphan Asylum, and the United Hebrew Charities. If the institutions refuse to consolidate the money reverts to the residuary estate.

The Waltham (Mass.) Hospital has received the gift of $5,000 to endow a bed in the children's ward to be known as the "Sally Hope bed."

Beth Israel Hospital.—The plan for a new building for Beth Israel Hospital was put into definite form recently when a meeting was held at the Hotel Savoy to discuss the matter, and a General Building Committee was appointed. Gifts to the building fund amounting to $100,000, in addition to $60,000 previously contributed, were announced.

New Amsterdam Eye and Ear Hospital.—According to the annual report of this institution, 4,623 cases were treated during the year ending September 30, 1908, and 3,349 prescriptions were dispensed. The total number of visits made was 7,777. The slight reduction in the number of cases from those treated last year is due to the fact that applications for free treatment have been more carefully investigated, and many have been considered unworthy.

Lincoln Hospital.—It has been suggested the Lincoln centennial year might be appropriately celebrated by the endowment of the Lincoln Hospital in New York as a perpetual monument. Half a million dollars is required, and plans for raising the amount are under consideration.

Memorial Hospital.—Port Arthur, Texas, is soon to have a new hospital, which will be erected by Mr. John W. Gates as a memorial to his mother who died recently at her home in that city.

New Head for Bellevue.—Dr. Winford Henry Smith, superintendent of the Hartford Hospital, of Hartford, Conn., was selected as general medical superintendent of Bellevue and Allied Hospitals at a meeting of the trustees on January 16. Dr. Smith, who is only a little over thirty years of age, was graduated from the Johns Hopkins Medical School in 1903. He has had hospital experience at the Lakeside Hospital in Cleveland, and the Kingston Avenue Hospital in Brooklyn. In March, 1906, he became superintendent of the Hartford Hospital. It is hoped that Dr. Smith may take up his new work in New York by the first of February.

The Duty on Surgical Instruments and Scientific Apparatus.—The president and secretary of the American Hospital Association have issued a circular requesting the cooperation and assistance of hospital superintendents and trustees towards securing a reduction in the tariff on surgical instruments and scientific appliances. A petition has been made to the Chairman of the Ways and Means Committee of the House of Representatives, suggesting the following amendment to Paragraph 638 of the present tariff act. The section in italics is new. Philosophical and scientific apparatus, utensils, instruments, and preparations, including bottles and boxes containing the same specially imported in good faith for the use and by order of any society or institution incorporated or established solely for religious, philosophical, educational, scientific, or literary purposes, or for the encouragement of the fine arts, or for the use or by order

of any college, academy, school or seminary of learning in the United States, or any State or public library, and not for sale, *and all medical and surgical instruments, appliances, and apparatus specially imported in good faith for the use and by order of any incorporated hospital, asylum, or other institution rendering medical or surgical aid to the public or any portion thereof free of charge, and whose expenses are borne wholly or in part by public funds or by private subscription, said articles to remain the permanent property of such hospital, asylum, or other institution,* subject to such regulations as the Secretary of the Treasury shall prescribe.

Fire in Insane Asylum.—A fire which broke out in the laundry of the hospital for the insane at St. John, New Brunswick, recently, caused a loss of about $60,000. The 400 patients were removed without loss of life, only one receiving minor injuries.

Emergency Accident Relief Stations.—Plans are being devised for establishing accident relief stations in the downtown districts of Chicago, to be known as the Iroquois Memorial Stations. At the meeting between Health Commissioner Evans and Dr. George J. Tobias, the latter president of the Iroquois Memorial Association, plans were discussed for remodeling the city property at 87 Market street, so that the first station may be begun in May next, and turned over to the city on the sixth anniversary of the Iroquois Theater Fire.

Hospital Saturday and Sunday Association.—The annual meeting of this association was held on January 12, at the United Charities Building, New York, and officers were elected for the ensuing year as follows: *President,* George Macculloch Miller; *Vice-President,* Isaac Stern; *Treasurer,* Charles Lanier; *Recording Secretary,* George P. Cammann; *Corresponding Secretary,* the Rev. Dr. George S. Baker. Andrew C. Zabriskie and Julius Robertson were elected to fill vacancies on the board of trustees. The general agent reported that the indications were that the collection now in progress would exceed by several thousand dollars that of last year, when $83,765.90 was realized.

The Illinois Board of Health, at a meeting held January 15, passed a resolution recommending to the governor the creation of a State sanatorium for consumptives, providing cities and villages did not take advantage of the power conferred upon them to erect municipal hospitals, and asking for an appropriation for the creation of a State colony for epileptics. The board also determined to continue its crusade against consumption during the coming year and to make a thorough investigation into the milk supply of the State, with the view of determining how far milk was responsible for the dissemination of various infectious diseases. The following officers were elected: *President,* Dr. George W. Webster, Chicago; *Secretary and Executive Officer,* Dr. J. A. Egan, Springfield.

The Chicago Ophthalmological Society, at its annual meeting, held January 11, elected the following officers: *President,* Dr. Frank Allport; *Secretary,* Dr. Willis O. Nance; *Councilor of the Chicago Medical Society,* Dr. Thomas Faith.

The King County (Wash.) Medical Society, at its annual meeting in Seattle, on January 4, elected the following officers: *President,* Dr. Grant Calhoun; *Vice-President,* Dr. Robert M. Stith; *Secretary,* Dr. Louis H. Redon; *Treasurer,* Dr. H. C. Ostrom.

The Lane County (Ore.) Medical Society held its annual meeting on January 2 and elected the following officers for the ensuing year: *President,* Dr. W. Kuykendall; *Vice-President,* Dr. A. W. Kime of Cottage Grove; *Secretary and Treasurer,* Dr. J. F. Titus; *Board of Trustees and Censors,* Dr. L. W. Brown, Dr. F. W. Prentice, and Dr. L. E. McDougal

The Tremont County (Col.) Medical Society, at its annual meeting on January 4, elected the following officers: *President,* Dr. J. D. Cummings of Florence; *Vice-President,* Dr. Clark of Canon City; *Secretary,* Dr. Goodlow of Canon City. Dr. J. W. Rambo of Portland was chosen as delegate to the State Medical Society meeting.

The Quinebaug (Mass.) Medical Society was organized, on January 6, with the election of the following officers: *President,* Dr. Reed; *Vice-President,* Dr. Olin; *Secretary,* Dr. Page; *Treasurer,* Dr. Webster.

The Scott County (Ia.) Medical Society held its annual meeting on January 7, at which the following officers were elected: *President,* Dr. William H. Rendleman; *Vice-President,* Dr. G. F. Harkness; *Secretary and Treasurer,* Dr. John V. Littig; *Delegate to the Iowa State Medical Society* in Dubuque in May, *Dr. Edward F. Strohbehn.*

The Holt County (Mo.) Medical Society, at its annual meeting on January 7, elected the following officers: *President,* Dr. J. M. Tracy; *Vice-President,* Dr. B. F. Quigley; *Secretary,* Dr. J. T. Chandler; *Treasurer,* Dr. C. L. Evans.

The Polk County (Ia.) Medical Association, at its meeting on January 5, elected the following officers: *President,* Dr. A. R. Ames; *Vice-President,* Dr. R. L. Parker; *Secretary,* Dr. Osbourne; *Treasurer,* Dr. Eli Grimes.

The New London (Conn.) Medical Society held its annual election and banquet on January 7. The following officers were elected: *President,* Dr. Daniel Sullivan; *Vice-President,* Dr. William M. Hill; *Secretary-Treasurer,* Dr. H. H. Heyer; *Librarian,* Dr. F. W. Hewes.

The Fayette County (Ala.) Medical Society, on January 5, elected the following officers for the ensuing year: *President,* Dr. Claud Bell; *Vice-President,* Dr. W. A. Graham; *Secretary,* Dr. C. B. Blackburn.

The New York Pathological Society.—At the annual meeting of this society, held on January 13, the following officers were elected for the ensuing year: *President,* Dr. Horst Oertel; *Vice-President,* Dr. Richard M. Pearce; *Secretary and Editor,* Dr. Karl M. Vogel; *Treasurer,* Dr. George C. Freeborn. Dr. Harlow Brooks and Dr. F. C. Wood were elected trustees of the Society for the term of three years.

Dr. Douglas Argyll Robertson died recently in India, at the age of seventy-two years. He was born in Edinburgh, in 1837, and was the son of a well known Scottish surgeon. He was a graduate of the University of Edinburgh and was later lecturer there on ophthalmology. He was at one time president of the Royal College of Surgeons, Edinburgh. Of late years he had resided, on account of his health, in the island of Jersey. His name is known to every practitioner of medicine through the Argyll-Robertson pupil, which he was the first

to describe, or at least of which he was the first to recognize the significance in tabes dorsalis.

Obituary Notes.—Dr. Henry D. Sill of Cooperstown, N. Y., died at his home on January 11, after a short illness, with typhoid fever, aged 42 years. Dr. Sill was graduated from the College of Physicians and Surgeons in New York in 1892, and after serving as an interne in St. Francis' Hospital for nine months began the practice of medicine at Cooperstown. He was a member of the American Medical Association and attending physician to the Thanksgiving Hospital of Cooperstown.

Dr. Horace C. Geyer of New York died on January 9, of diabetes, at Frankfort, Germany, where he had gone for treatment. Dr. Geyer, who was thirty-one years of age, was a graduate of the College of the City of New York and of the College of Physicians and Surgeons in New York, and a member of the Alumni of the Roosevelt Hospital.

Dr. Charles Denison died at Denver, Col., on January 10, of gangrene of the liver and septicemia following perforation of the gall-bladder by a gallstone. Dr. Denison was born in 1845, at Royalton, Vt., and was graduated from Williams College in 1867, and from the medical department of the University of Vermont in 1869. Because of pulmonary trouble, he removed to Denver in 1873, and for fourteen years held the position of Professor of Diseases of the Chest and of Climatology in the University of Denver, being made professor emeritus on his retirement. He had written largely on the subject of tuberculosis in the fight against which he was much interested. In 1890 he was elected president of the American Climatology Association; in 1901 he served as honorary vice-president of the British Congress on Tuberculosis, and was American corresponding member of the International Central Bureau for the Prevention of Tuberculosis in Berlin in 1902.

Dr. Henry Louis Goodman of New York died suddenly on January 12, aged 36 years. Dr. Goodman was graduated from Washington University, St. Louis, in 1893, and had studied also in Vienna and Heidelberg. Since 1899 he had been connected with the Department of Health as a medical inspector. He was a member of the American Medical Association and of the Alumni Association of the City Hospital. Dr. Goodman had been in poor health for some months past.

Dr. Andrew Henry Getty of Athens, N. Y., died at his home on January 14, aged 60 years. He received his medical degree from the University of the State of New York in 1897.

Dr. James Andrews De Wolf, surgeon-general of Trinidad since 1901, died on January 2, at Port of Spain, Trinidad. Dr. De Wolf was graduated from Brown University in 1861, served through the Civil War with the First Rhode Island Volunteers, and later was on the staff of St. Luke's and the Women's Hospitals of New York.

Dr. Arthur Ward King of Cleveland, Ohio, died suddenly on January 8, aged 26 years. Dr. King was graduated from the Cleveland Homeopathic College in 1905.

Dr. Irving B. Hayes of Florence, Mass., was instantly killed in El Paso, Texas, on January 3, while attempting to alight from a moving train. Dr. Hayes was on his way home from a journey to California. He was a graduate of Dartmouth College in the class of 1888, and of the Long Island College Hospital in 1899. He was 47 years of age.

Dr. Roscoe E. Brown of Everett, Mass., died on January 7, after several months' illness, aged 57 years. Dr. Brown was graduated from Bowdoin College in 1876, and ten years later settled in Everett, where he had since practised. He was a member of the Massachusetts Medical Society and the first president of the Everett Medical Society, attending physician to the Whidden Hospital, a member of the Board of Health and a former city physician.

Dr. George W. Lewman of Louisville, Ky., died of uremic poisoning on January 6, aged 75 years. He was graduated from the Cincinnati College of Medicine in 1858, but had been largely engaged in business activities. He was a veteran of the Civil War.

Dr. William B. Anderson of Vincennes, Ind., died at his home on January 4, aged 69 years. Dr. Anderson was graduated from the medical department of the University of Louisville in 1859, and served through the Civil War as a surgeon in the Confederate Army.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CHRISTMAS IN HOSPITALS—THE POLYCLINIC—DEBATE ON WHOOPING COUGH—UNIFORM ACCOUNTS FOR HOSPITALS—LONDON CHARITIES—OBITUARY.

London, January 1, 1909.

My last letter was sent off on Christmas eve. Now we began a new year. The week so far as hospitals are concerned has been occupied with very vigorous efforts to bring cheerfulness and courage to the patients. The children's wards and children's hospitals have generally been scenes of mirth. Christmas trees loaded with toys and other gifts have delighted many of the little sick ones. But adults have not been forgotten. Entertainments of various kinds—concerts, theatrical, and so on—have been gotten up by the students and nurses and the staffs, both medical and administrative. Benevolent visitors joined their exertions to relieve the tedium of a Christmas in hospital. Subscribers and others interested in the several institutions sent turkeys, game, choice fruits and other delicacies for those patients who could partake of them, and altogether the season must have brought a considerable degree of happiness to the afflicted patients.

The polyclinic is in a bad way—financially. It is said to be some £500 in debt, and for this sum is to be closed, at any rate partially. Various rumors about it have been in circulation for a few weeks, but the crisis seems now to have come, for Sir Jonathan Hutchinson, at his last demonstration, made a statement on the matter, from which I gather that those associated with him, the council or committee, are not inclined to take any share of the burden of debt or to encourage further expenditure. Accordingly, as the building is taken in his name, Sir Jonathan is responsible for the rent. It seems rather hard that he should be left in the lurch, especially as he has been the mainstay of the institution and has presented it with his remarkable museum. It would be a disgrace for that collection to be distributed, and if the council do nothing for its preservation the profession might well come to the rescue. I hope there may be no need of this, for Sir Jonathan stated that whatever happened he should continue to be present on his days to give demonstrations on cases brought before him for the purpose. All who have attended these demonstrations know how every minute detail of a case is investigated by him and how valuable are his clinical remarks.

Whooping cough has been the subject of a discussion at the Section for Children's Diseases of the Royal Medical Society. It was opened by Dr. Porter Parkinson, who said two-thirds of the deaths from this disease took place in the first year of life and most of them were due to lung complications. He thought there must be a specific organism, though the real one has not been isolated. Epidemics on board ship seemed

to show that the virus remained active for weeks. Half the cases occur under two years of age and it is not uncommon under six months. He mentioned a case in a child of twelve days, whose mother was suffering from it. The primary disease may be overlooked when bronchitis or pneumonia has set in, as then the whoop may disappear. Paroxysmal cough arising otherwise may also be mistaken for it. Dr. Parkinson referred to treatment by diet and drugs. He could recommend bromoform in solution, 1 minim to 1 ounce of water, with a few drops of alcohol. Of this he gave from 1 to 6 drams.

Dr. L. Guthrie, referring to the history of the disease, said the term "chin-cough" survived in some places—perhaps from "la quintaine" or "tussis quintana," by which it was known in Paris in 1578, as it was supposed that the paroxysms occurred at intervals of five hours. He thought that paroxysmal coughs due to enlarged glands mostly occurred in those who had had whooping cough. He had seen a death after a paroxysm in a boy of three who died in the out-patient's waiting room. Bromide and belladonna were his favorite drugs.

Dr. Walter Carr said in doubtful cases the diagnosis lay between influenza, enlarged bronchial glands, and bronchiectasis. In the last the cough stopped just short of the whoop. Fresh air at a temperature of 60° was of great value. Too much drugging interfered with the alimentary canal. He had tried vapors and fumes, but doubted their efficacy. He thought potassium bromide had a value and rubbing with a liniment. Belladonna was useful in the late stage. When a child was vomiting constantly it was well to give it a little food to bring on a paroxysm and immediately after that a little more food, which would often be retained.

Dr. J. D. Rolleston gave some statistics of the asylums board hospitals. He did not think the disease had a very unfavorable effect on other acute infections with which it might be associated. Indeed, such association is rare. In diphtheria the laryngeal effect is greater if whooping cough is concurrent. He could not confirm Trousseau's observation that whooping disappeared during scarlatina.

Dr. Ewart pointed to the serious sequelæ and recommended systematic hygiene of the upper air passages, with a view of inhibiting the growth of microorganisms. He had seen relief follow instillation of oil into the nostrils. Potassium iodide was useful, so was terebene, both as inhalation and in liniment. A respiratory belt as advocated by Kilmer was good.

Dr. Milner Burgess said little had been added to our knowledge of the disease during the last eight years. In an experience of over thirty years he had only met with one case of meningeal hemorrhage. Why was this so infrequent? He laid stress on liquid food in small quantities, given immediately after the paroxysms.

Dr. Spriggs replied to the last speaker's inquiry and said it had been shown experimentally that blood-pressure might be enormously increased without injury to healthy vessels.

Dr. Francis Nunn recalled the old popular plan of sending a child to the gas works and actually suggested that the gas might be turned on for a few minutes in the patient's room! Dr. Biernachi approved of taking children to gas works and thought the benefit probably due to waste products rather than to escaped gas.

Dr. Russell Wells thought the symptoms due to increased excitability of a portion of the nervous system connected with the vagi and probably originating in a toxin. He had therefore tried cocaine by the mouth, calculating the dose according to age on the basis of 1 grain three times a day for an adult. He had seen no ill effects. In children there was no danger of forming a habit.

Dr. Parkinson thought this treatment risky.

Dr. L. Goffe, after syringing the ears with boric lotion, painted the external auditory meatus with a strong solution of cocaine.

Dr. B. Bailey said in the Shadwell Hospital the experience pointed to the disease ceasing to be infective after six weeks.

Dr. Meredith Richards thought the risk of infection was greatest in the early stage. He excluded children from the schools for five weeks and contacts for a month.

Dr. George Carpenter said of 466 out-patients chiefly below the school age only one was associated with varicella, two with scarlatina, and a few with measles. Among complications he noted hemoplysis, hematuriaa, subconjunctival hemorrhages, purpura, black eyes, and enlarged cervical glands. Four cases developed the whooping habit, which persisted for years. He doubted if papillitis indicated meningitis. The unconsciousness associated with the convulsions might last twenty-four to forty-eight hours. He had no faith in any specific treatment.

Mr. Clement Young presented for inspection a young man of twenty-one with a remarkable deformity of the chest and dwarfing of stature originating in whooping cough at the age of four. The thorax below the level of the nipples on both sides, apparently due to collapse of the lung in childhood. He is only 5 feet high and weighs 60 to 100 pounds. He has fair health, but dyspnea on exertion or mounting stairs is a difficulty for him.

The three hospital funds have again directed attention to the revised uniform system of accounts. A circular has been issued dealing with the questions that have arisen out of the first year's experience of the system. It includes too amended forms of income and expenditure accounts, balance sheets, and statistical tables of expenditure upon in- and out-patients. The amended regulations will have to be complied with by all institutions that apply for grants from either of the three funds.

The thirty-fourth Directory of the Metropolitan Charities has appeared. The total contributed during the year 1907-1908 is estimated as £7,743,000. Out of the amount contributed to hospitals, dispensaries, and nursing institutions, which was £1,252,542, that which was for the general hospitals amounted to £641,628.

Surgeon-General John Edward Tuson, M.D., F.R.C.S., died on the 24th of December, aged 79.

Dr. Robertson of Glasgow died December 16, aged 75. After serving for a long period as superintendent of the City Hospital, he was elected physician to the Royal Infirmary. He had served as president of the Glasgow Pathological and Clinical Society and held other offices. His health failed of late and he died suddenly from cardiac failure.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 7, 1909.

Some Aspects of Psychotherapy.—J. J. Thomas says, among other things, the following on the so-called "Emmanuel Movement." He does not wish to be understood as opposing the broadening of the work of any church, feeling that this particular idea is one for the churches to consider according to their individual needs and situations. It seems to him, however, that the moral bearings which arise in certain cases of functional nervous disease are better treated by physicians than by clergymen, just as the moral bearings of venereal disease and the sexual relations can be and are better handled by the physician as they are being handled in the broadest and best way by many conscientious Christian physicians, every day of their lives. The introduction of religious sentiment, not to say religious sentimentality, into the treatment of psychic disorders is distinctly harmful. Finally the careful individual study required for the proper selection of the method best adapted to the cure of the parbenten case precludes their being treated and handled in numbers in classes. All methods of treatment of disease are with greater safety left in the hands of medical men, and by cooperation with clergymen in the future as in the past, the often perplexing moral and religious questions that may arise in these curious functional nervous disorders can be best met. This presupposes, however, that medical men, at least those fitted for the work, shall interest and inform themselves of methods of study and treatment of such cases or the latter will fall into the hands of quacks and pretenders to treat, and because of the possibility of cure by suggestion, will spread the fame of this unscrupulous class.

New York Medical Journal, January 9, 1909.

Puerperal Sepsis.—H. Weil says that at the present time the following facts are definitely assured: (1) The uterine walls can and do absorb, and this power is greater following abortion and labor with its more numerous veins and lymphatics. (2) The products of germ metabolism are poisonous; these poisons called toxines, when derived from pathogenic bacteria, are capable of producing violent symptoms and death when injected into animals. (3) The

lochial discharges of a puerperal infection are loaded with pathogenic germs and toxine. Each of these facts is easily demonstrated and incontestable. This being the case, it only remains to demonstrate that, (4) absorption plays an important part in the disease. Of this there can be little doubt. Perhaps the most convincing proof lies in the fact that we produce identical symptoms by the injection of isolated toxine easily obtained in this disease by repeatedly filtering the lochia. Again, there are diseases, such as diphtheria and tetanus, in which the bacterial growth is comparatively limited, yet absorption of the toxin causes profound symptoms, or even death. The entire theory of serum therapy is based upon toxine absorption. If these four hypotheses are conceded, it is our clear duty to apply active drainage to every case that resists curettage, and we fail in our duty if we stand idly by and permit our patients slowly to poison themselves, while we pin our faith to such procedures as high enemas and intravenous injections, which every physician realizes are useless except that "they cannot possibly do any harm—besides impressing the patient and her friends," etc. Intrauterine irrigation also possesses these latter virtues.

Myocarditis.—A general description of the disease is given by P. H. Markley, who notes that besides the infections, the etiological factors concerned in the causation of fatty degeneration include all prolonged nutritional disorders, such as phthisis, carcinoma, and the primary anemias; and evidences of cardiac enfeeblement occurring during the course of these affections, should always arouse suspicion. In fatty degeneration the symptoms are negative, until dilatation occurs, which is generally early, when, instead of the increased arterial pressure, so constantly present in the fibroid form of myocarditis, we have a lowering of blood pressure, and in place of the angenoid attacks of fibrosis, apoplectiform seizures are more frequent, closely resembling true cerebral hemorrhage, even to hemiplegia, stertorous breathing, unconsciousness, and Cheyne-Stokes respiration. In such cases the distinction from true cerebral apoplexy depends almost entirely upon the fact that in cerebral hemorrhage the pulse is of high tension, so that it becomes important to keep constantly in mind the low tension pulse of fatty degeneration. Other than these exceptions, the symptoms of cardiac enfeeblement found in connection with the two forms of degeneration do not materially differ, and may be combined because of the possible coexistence of the two conditions, nor is their distinction important as regards the treatment, while the prognosis is equally unfavorable in each.

The Relationship Between Dental Caries and Systemic Disturbances.—W. J. Lederer refers to the various disordered bodily states accompanied by dental caries and other lesions. He notes that from various circulatory disturbances the teeth and alveolar structures are more disposed to disease than many other tissues because they are end organs, traverse solid bone structures ,and cannot yield as do the peripheral vessels of other end organs. They therefore fall a prey to disease quicker than do other end vessels. All systemic disturbances which modify the circulation of the gums and teeth,all diseases attended by increased arterial tension are liable to set up dental lesions. A list of the common causes affecting vascular tension is given by the author. He speaks of the dental lesions excited by pregnancy and menstrual disorders, and calls attention to the dental symptoms of tabes as follows: (1) Painless pulps; (2) atrophy of gum; (3) absorption of alveolar process; (4) spontaneous, painless shedding of teeth; (5) spontaneous suppurative conditions of the maxillæ with necrosis; (6) patients sometimes experience a sort of drawing facial neuralgia, which is followed by a sensation as though the teeth are elongated and the gums and lips are swelling, but there is no sign of inflammation. Finally in treating buccal conditions which resist local treatment, one must remember the possibility of underlying circulatory disturbances, nervous disorders, nutritive diseases, infections, and various other abnormal physiological conditions.

Spontaneous Absorption of Incipient Cataract.—S. Moschkowitz reports the case of a draughtsman of thirty-one years whose vision had been failing him for two months, especially in the left eye. Examination showed a cataract situated in the center of the lens close on to the anterior capsule, occupying nearly the whole surface of the lens. It was determined to wait for the ripening of the cataract and then operate. There being a rheumatic history, sodium salicylate was given and later the iodide. Two applications of galvanism were made and were followed by very slight reaction. In about a month from the first visit, the lens was perfectly clear.

Journal of the American Medical Association, January 9, 1909.

Functional Neuroses.—Speaking of the modern tendency to nonmedical treatment of disease as shown in Eddyism, the so-called Emmanuel movement, etc., J. Collins considers the medical profession to be, to some extent, responsible. He thinks that until recently the general practitioner has had little instruction in regard to disorders of the nervous system, and more especially the so-called functional diseases. He thinks that there is still a trace of the old idea of moral perversion in these cases—a sort of relic of the old idea of demoniacal possession. The idea of reflex influence has also its part and still another reason is the fact that psychology is still an unknown department of knowledge to the majority of general practitioners. The average physician, moreover, is at a loss how to proceed with the necessary examination with these functional cases. He undertakes their treatment with a very indefinite diagnosis, if any. If medical students, he says, were given even an elementary course in psychology their attitude towards their patients and toward the psychic symptoms they present, not only in nervous diseases but in many other diseases, would be different from what it frequently is. He takes up especially the Emmanuel movement, which is having such a vogue in certain quarters at the present time, and thinks that the clergymen engaged in it are going beyond their proper province and that they might more becomingly display some little measure of the quality displayed so prominently by the Founder of our religion, viz., humility. He quotes from the utterances of Dr. Worcester and Bishop Fallows to show that they misunderstand the position of physicians on these subjects and, in fact, the whole subject on which they claim to be experts, especially as regards the frequency of functional nervous diseases in modern times. Their claims of success, too, he considers very extravagant and their zeal not all according to knowledge.

Psychotherapy.—R. T. Edes discusses the present status of psychotherapy. He says that the boundary line between functional and organic disease is yet far from settled. New discoveries are constantly narrowing the list of maladies of which the organic substratum is unknown. At present the doctrine of the dependence on bodily health of correct mental action which is far the most potent theory for good, he says, is now in the minds of hundreds of thousands being reversed and mental action is supposed by them to control bodily structure. He does not deny the influence of the will, but it has its limitations and he shows how many physicians depend more or less on moral effect in their practice and how essential is faith as a factor in all psychic cures. He analyzes the methods of reaching the lower consciousness and shows how improbable it would be to lead a sincere, well-instructed student without tact, to become a successful mind healer. His sensitiveness and care for his scientific reputation would be liable to be insuperable obstacles. Among the elements of psychotherapy or the avenues of approach, Edes includes deception and placebos, which can only be employed, at least, to a very limited degree, by the conscientious physician, though there is nothing in the other methods enumerated which may not be legitimate. Hypnotism is considered by him of a certain value and the disadvantages of its possible use for criminal purposes, the impairment of the patient's will, and the liability of inducing too great dependence of the patient on the mere personality of the physician are not regarded by him as objections of great weight. There is more peril, he seems to think, in the impairment of the physician's influence for legitimate persuasion by unsuccessful attempts at hypnotism. Only a certain proportion of persons are hypnotizable. Freud's method is noticed at some length. It has, he thinks, probabilities in its favor, but the vast amount of time and patience that it requires may put it out of the power of many to employ it, even those otherwise qualified. In conclusion he notices briefly the movement for the alliance of the church and medicine, which he does not disparage and considers that in some cases it may be helpful.

Cranial Technique.—F. Hartley enumerates the following as the prime requisites for avoiding the dangers of shock and sepsis in operations on the brain: 1. Instruments which will open the skull quickly over any desired area and to any extent. These are the motor saw and guard, osteotone, drill, fraise, and meas-

ure. 2. A method of craniocerebral topography permitting an accurate exposure of the desired area. Chipault's is the best method, adapted to the skull of all ages, races or individual peculiarities. 3. Osteoplastic flaps cut so that they will expose the desired area in the easiest manner. 4. The replacing of the bone flap in every possible case or the covering the defect with an accurately fitting foreign material (celluloid or aluminum). He prefers autoplasty when possible. 5. The most perfect hemostasis in the preliminary as well as in the final steps of the operation. The operation he divides into two steps, the first concerned only with the skull, the final with the dura and brain. All drugs should be given up several days before operating, and a record of pulse rate and blood-pressure should be taken twenty-four hours before operation. The patient's head is raised on the table between 15 and 30 degrees, which Hartley has found sufficient to stop venous bleeding and lower arterial pressure. He has not been able to compare the effects of Crile's rubber suit and carotid compression or of Dawbarn's sequestration-anemia with this, but if they will improve the arterial pressure better than elevation and with no greater danger of inducing sudden syncope, he will certainly use them. During the operation he would have the blood-pressure recorded by the anesthetist by a sphygmomanometer on the arm, as a sudden fall will warn the operator of any impending sudden collapse, and will probably enable us to avoid the 25 per cent. of sudden deaths following prolonged operations. The details of the two steps of the operation are given and the necessity of careful hemostasis during the second stage emphasized, as well as the importance of avoiding infection of the lateral ventricles. Possible later complications are: 1. Shock, in prolonged operations with hemorrhage or after large tumors have been removed and the cerebral statics disturbed by the space left. In such case the acute cerebral edema of von Bergmann occurs. To avoid this Hartley tampons and gives counter-pressure through the flap. 2. Hyperpyrexia: This occurs after both severe and moderate handling of the brain, especially if the ventricles have been opened, and is due to toxicity of the neoplasm secretion, infection or irritation of thermic centers in the bulb. 3. Encephalomeningitis may be due to injury or to infection from the patient's blood or without. It usually appears during the first month after operation, coming on slowly with localized convulsions, contractures, paralyses, somnolence, mental torpor or delirium. 4. Hernia may be present at the time of operation as a tumor of the base or as a voluminous tumor of the centrum ovale, or at a later period in the form of encephalitis. The latter part of the article is given to the recently reported results.

Nasal and Sinus Brain Affections.—C. G. Coakley says that nasal infection can extend to the brain through the blood, the lymphatics, or by necrosis or perforation of the sinus walls. There is a small portion of the venous blood from the nose that passes into the superior longitudinal sinus through the foramen cecum, and the perineural lymph spaces around the branches of the olfactory nerve are so arranged that it is easy to understand how infective meningitis may arise from infection along this route. He goes, with considerable detail, into the possibilities of brain infection through sinus disease, either suppurative, polypoid, or otherwise. Direct perforation of the posterior wall of the frontal sinus is rare according to his observation, but necrosis of the inferior or orbital wall is quite common. Ethmoidal brain infection may occur through necrosis or rupture of the cribiform plate and the thinness of portions of the superior and outer wall of the sphenoid cavity make it easy to understand how they may become ruptured from obstruction of the outlet for a purulent secretion. These causal conditions are sometimes difficult to detect, and Coakley points out why this is the case. There is an acute form of meningitis, he says, involving the cord as well as the brain, which is nearly always fatal, in which his sinus examinations have been unsatisfactory and in which he has never felt willing to advise operation. In the less acute type, commonly called serous meningitis, if sinus disease exists he believes operation is justified as in otitic infection. When sinus disease has long existed in some chronic cases, if other source of infection can be excluded, he would advise operation as in serous meningitis. The operative technique he finds most satisfactory in exploring the sinuses as by what is known as the ethmoidal route, opening at once into the anterior group of ethmoidal cells alongside the orbit. By following this back through the whole of the ethmoid labyrinth and opening and enlarging the sphenoid sinus, one traverses and explores very thoroughly the region from which most infections reach the cranial and orbital cavities. One is working by this route parallel with the floor of the cranium and is much less liable to perforate it than by the maxillary operation advocated by some. It is a bloody operation and should be undertaken only by one able to reflect light into the cavity so as to see into the depths of the ethmoid and sphenoid regions. The floor of the frontal sinus can be removed and the cavity probed to find whether it is the seat of trouble. If so it can also be operated on by working through the frontal bone from an incision through the eyebrow and reflection of the periosteum. A short operation is usually advisable in these desperate cases, and Coakley does not recommend the thoroughness used in suppurative sinusitis without cranial complication, but would exenterate the cells as quickly as possible, introduce iodoform gauze drainage through the opening, and leave the wound open without any attempt at suture. Should the patient recover from his acute symptoms, secondary suturing may be done in the course of a few days with but little more scar than if the wound had been closed at the time of operation.

Diphtheria "Carriers."—M. Solis-Cohen believes that the latent and "carrier" cases are mostly responsible for the spread of diphtheria in cities where the usual precautions are taken as to notification, etc. He gives his own results in the examination of those who had come in contact with diphtheria and quotes those compiled by Graham-Smith which correspond fairly well with his own, which showed an average of over 60 per cent. infected. The infected "contact" is, therefore, as great a menace to public health as the convalescent from actual diphtheria. He defines as "latent" diphtheria the condition in which positive cultures are found in persons showing some pathological condition, local or general, unassociated with pseudomembrane. Some of those cases may possibly be only tonsilitis. The fact that nonvirulent diphtheria-like bacilli are found in the mouths of healthy persons complicates the question, but Solis-Cohen thinks that health officials would be justified in demanding bacteriological tests of those who had been in contact or inmates of the same house or institution with a diphtheria patient, and, if found infected, isolating them till the bacilli disappear. But, owing to the possibility of the organisms being nonvirulent, inoculation tests should be made when requested on guinea-pigs, and restrictions removed if the animal survives. He has followed this plan in his practice, and as medical inspector, whenever possible, since September, 1906, with good results, and relates a number of instances showing its utility.

Prophylaxis of Infectious Diseases.—D. L. Edsall considers the duty of the practitioner in relation to the prophylaxis of infectious diseases. He points out that the education of the public in regard to this matter is largely in the hands of the practising physician, who not only has it in his power to disseminate expert knowledge, but also holds the key to the defense against disease at the critical moment. A little neglect at a favorable time for spreading infection may convert what should have been an isolated case into an epidemic. The reality of the danger of infectious disease is evident, the question is how it is transmitted and how readily, and how such transmission can be prevented. Edsall gives illustrations of contact infection and of other often unsuspected methods of transmission of serious disorders, and points out the necessity of restricting intercourse with sufferers from these ailments. We should take earnest care, he says, to acquaint those who come in contact with the sick, and especially those in attendance on them, with the ways in which they may acquire the disease or convey it to others, not merely giving hasty directions that will be neglected, but insisting on their importance and seeing to their observance. Even in hospitals there is too much laxity in this regard. Lastly, he insists on physicians themselves adopting all due precautions, not only for their own safety and that of others, but also because their example is what the laity will look up to and follow.

The Lancet, January 2, 1909.

Family Tendency to Relapse in Scarlet Fever.—Four instances of this tendency are recorded by C. Beards, three of them illustrating the complementary nature of the

primary and secondary attacks. In many cases of scarlatinal relapse the secondary attack is severe after primary has been mild, and vice versa. A sample history is here summarized, all the cases here recorded being in the same family. A boy of eleven was admitted to hospital October 11, 1907, on the fourth day of the disease, with a fading rash, swollen tonsils and fauces, tender cervical glands, and a peeling tongue. Four days later the temperature was normal and disquamation appeared. This continued in a normal manner till November 10, when the symptoms of invasion returned in a more severe form than in the primary attack, and were attended with well-marked secondary adenitis and rheumatism. Two days later a secondary desquamation began and followed the usual course.

A Prospective Cure for Elephantiasis.—W. S. Handley commends the operation of lymphangroplasty, in which a number of stout silk threads running the entire length of the limb are introduced into the subcutaneous tissues of the swollen part and are completely and permanently buried. Their capillary action enables them to replace the trunk lymphatics and to transfer the excess of fluid from the area of lymphatic edema to regions in which the lymphatic circulation is normal and from which consequently the excess of fluid is absorbed and carried off into the general circulation. Elephantiasis differs from the lymphatic edema seen in connection with mammary cancer in that the lymph of the swollen arm is a sterile fluid, while in elephantiasis there is a chronic infection of the tissues with micrococci. Vaccination against the infective micrococci, although powerless in itself to reduce the edema, would appear in elephantiasis to be an essential preliminary to the operation of lymphangioplasty. One favorable case is reported on the plan of treatment above referred to.

Acromegaly with Illustrative Cases.—G. Rankin and R. O. Moon give a general description of this affection, with photographs of two cases. Regarding treatment, they note that at the present time reliance is placed almost exclusively on pituitary and thyroid extracts. Thyroid extract must always be given cautiously, lest it accelerate the decline of strength and induce a permanent glycosuria. Pituitary body extract is preferable and good seems to follow in some cases. Except in cases with a definite specific taint, the iodides and mercurials are useless. The general health of the patient must be carefully watched. Dietetic measures may rid the patient of glycosuria. Constipation calls for simple aperients, fruit, and vegetables. The coal tar preparations will relieve the headaches. For the sweating, atropine, zinc oxide, and picrotoxin may be given. Frequent change of scene, massage, electricity, and hydrotherapy should all be resorted to under proper conditions.

Why and How Should the Surgeon Attempt to Preserve the Vermiform Appendix?—C. B. Keetley discusses this question, with special reference to the value of the appendix in the surgical treatment of constipation. He gives his personal experience with appendicostomy, appendicotomy, and appendix transplantation, states the uses, advantages, justifications, and drawbacks of these operations, and finally analyzes 36 personal cases. He aims to show (1) that transplantation of the appendix so that the whole or greater part of it from its root in the cecum lies permanently imbedded in the abdominal wall will produce the good results of excising it; (2) that the operation is practicable and safe, and (3) that in many cases the operation should be preferred to appendicectomy. His technique is described in full. Appendicostomy, he believes, to be the best surgical treatment for constipation yet devised. Strictly speaking, it is not a remedy for constipation, but an operation which facilitates the employment of remedies. It insures the enormous value of taking enough water into the alimentary canal and taking it at proper times. It can be further used to teach the advantage of not drinking copiously at meals. Many people, says the author, dilate the stomach, indirectly irritate the pylorus, and ultimately bring about constipation by taking too much beer or whisky-and-soda at meals, imagining that the food protects them from injury by alcohol.

British Medical Journal, January 2, 1909.

Adhesion of Soft Palate to Nasopharynx.—F. J. Hall refers to two children, aged 6 and 11 years, with every sign of adenoids, but examination under anesthesia revealed none, but there was a complete adhesion between the soft palate and pharynx. No instrument could be passed into the nasopharynx, but the adhesions were finally broken down with the finger. Bleeding was considerable, but the result was eminently satisfactory. The condition was probably congenital.

Persistent Thymus and Sudden Death.—S. H. Dankes reports the case of a woman who, pursued by her husband after a quarrel, suddenly fell dead. Autopsy revealed an enlarged thymus two and three-quarters inches long, two inches wide, and weighing one and three-quarters ounces. The coroner's verdict was that the woman died from excitement, mental and physical, causing heart failure, the persistent thymus being in some way a predisposing factor. The author notes that an enlarged thymus has frequently been found in cases of sudden death from apparently insufficient causes. The explanation of death in such instances is more likely to be found in the physiology rather than in the anatomy of the gland.

The Results of Operations for Carcinoma of the Tongue.—H. T. Butlin analyzes 197 cases, operated on by him in the course of twenty-seven years (1881-1908). His paper is largely a series of tabulations, not lending itself to abstracting. We may summarize a few of his most important statements. Died of operation, 20; lost sight of after operation, 1; died of recurrence in the mouth, 26; died of affections of the glands without recurrence in the mouth, 29; died of recurrence in the glands without recurrence in the mouth, 10; died of recurrence in mouth and glands, 7; died of recurrence uncertain whether in mouth or neck or both, 10; died of affection of the glands uncertain whether recurrence in the mouth, 3; died of recurrence in the glands uncertain whether recurrence in the mouth, 1; died of affection of glands on the other side of the neck, 2; died of secondary disease of lungs, 1; died of cancer of opposite border of tongue, 2; palliative operations (glands too advanced for removal, cancer of tongue only removed), 3; operation in tongue abandoned, 4; operation on glands abandoned, 1; cases not countable (operations performed within three years, the patients either died of other diseases within three years or are still alive and well within three years), 22; successful (all these patients lived for from three to twenty-two years, free from recurrence, most of them are still alive and well), 55; of the 20 deaths from operation, 10 died of septic pneumonia, 3 from subsequent bleeding, 2 from shock, and 1 each from sepsis of wound, acute mania (wound doing well), heart failure after some days, suffocation, and unknown cause.

Treatment of Chronic Rheumatic and Rheumatoid Arthritis by Radiant Heat and Cataphoresis.—Two cases are detailed by C. F. Bailey, who uses a heat apparatus consisting of a large lamp in a funnel-shaped projector lined with a reflecting surface. The lamp is powerful, using as much current as 24 of the ordinary 32 candle-power lamps. With this apparatus a dry heat of 400° F. can be obtained without damage to the skin. The general result of exposure is that the cutaneous and deeper vessels are dilated, the lymphatics are filled, the local arterial pressure is diminished, and the local metabolic processes are increased. The effects do not pass off at once and after repeated exposures they are more or less permanent. Besides their influence on the tissues, the rays also exert an influence on microorganisms and increase leucocytosis. The subjective effect is a relief of pain. Probably the anesthetic effect of the ultraviolet rays is responsible for this result. As soon as the application is over, cataphoresis with iodine "ions" immediately follows. Thus if a wrist is to be treated, it is immersed in an arm bath containing a 2 per cent. lithium iodide solution and either a large indifferent pad is placed on the back or the other hand is immersed in another arm bath, muriate of ammonia or common salt being used for the indifferent pad or bath. For the knee, lint wet with the lithium solution is wrapped around the joint. It is necessary to work with large currents.

Münchener medizinische Wochenschrift, December 29, 1908.

Deposition of Calcium Salts in the Shoulder Bursæ. Bergemann and Stieda have reported eight cases of acute inflammation of the subacromial and the subdeltoid bursæ, all of the cases showing marked shadows on examination with the *x*-rays. The symptoms consisted of pain and tenderness in the region of the bursæ and limitation of motion because of the pain; most of the patients did not

give any history of gout and no signs of this disease were present. The authors now report three new cases of the same symptom-complex in which they succeeded in obtaining the permission of the patients for removing the affected bursæ. In all cases areas of calcification were found so that gouty deposits were completely excluded. They think that the disease described is an independent affection having nothing in common with gout or rheumatism and only slightly dependent on trauma, which may lead to exacerbations of the symptoms already present.

Tuberculosis in Childhood.—Hamburger says that tuberculosis is properly to be considered as much a disease of childhood as measles. His tests with the new cutaneous reactions and with the old subcutaneous test have given positive results in over ninety per cent. of cases. The bacilli entering the organism of children may be confined in their action to local sites or more rarely may produce a tuberculous process throughout the body. Even if the disease enters a latent stage soon after its beginning in the organism of the child the appearance of tuberculosis in adult age simply means the flaring up of the old process and not at all a new infection with the bacilli. This explains the differences in the clinical pictures of tuberculosis in the young and in the adult. The former very seldom are attacked by chronic pulmonary disease but show localized lesions in the glands or a few separate lesions in the lungs. The typical tuberculosis of the lungs on the other hand is due to the long stage of preparation for the spread of the infection by the existence of latent disease or of a localized lesion. In a word, pulmonary tuberculosis must be looked upon simply as a recurrence of the tuberculous infection of childhood, and all the phenomena of the disease as due not to the original influence of the bacilli alone but much more to the changes in the organism produced by their presence for a long time.

Deutsche medizinische Wochenschrift, December 17 and 24, 1908.

Treatment of Acute Rheumatism.—Plehn says the findings of Lutjes according to whom the administration of salicylates leads to great irritation of the kidneys, which often is intense enough to call forth characteristic changes in the urine, have not been substantiated. The value of the drug as a specific in rheumatism, too, outweighs any possible injury to the kidneys, especially as the irritation of the kidneys is usually very transient in character, lasting no longer than the stomach symptoms that are sometimes produced by the salicylates. The success of salicylates in rheumatism depends upon two factors: the correctness of the diagnosis of the disease as acute articular rheumatism and the sufficiently large doses of the remedy. The acute onset or the history of such onset in the past is almost a *sine qua non* for the diagnosis in question. The treatment should consist in the immediate administration of salicylic acid in powder form in the dose of one gram every two hours so that the patient receives from three to five grams of the remedy by the evening of the day of diagnosis. No medication is given during the night, but on subsequent days about six grams of salicylic acid is administered each day; after the temperature has been normal for three days and the pain has disappeared the dosage is reduced to four grams per day for seven days; three further days in bed without the drug are insisted upon before the patient is allowed to get up. The painful joints are wrapped in cotton during the treatment and placed in the most comfortable position by means of pillows, etc. The drugs should be administered after meals whenever possible. No injury to a healthy heart has ever been observed by this treatment; no disturbances took place even in the presence of old valvular lesions. But little use has been found in the action of salicylates after a fresh endocarditis or a myocarditis.

French and Italian Journals.

Prognosis and Indications for Hebotomy.—Cyrille Jeannin and V. Callala give the prognosis of hebotomy as influenced by early and late accidents. Early accidents are hemorrhage, thrombosis, vulvovaginal tears, and urinary lesions; late accidents are impotence, genital prolapse, incontinence, persisting sciatica, and inguinal hernia; they are fortunately rare. The only cause of maternal mortality is infection; the mortality percentage in 5.7 for the mother, 7 for the child. Comparing symphyseotomy and hebotomy the authors find that hebotomy is the more satisfactory; the prognosis for both mother and child is better than in symphyseotomy. The only logical method to use in hebotomy is the open method, owing to the danger of perforating the bladder in the subcutaneous method. It is to be preferred to cesarean section only in diameters of more than 8.5 centimeters conjugate, when labor has begun. When dilatation is already complete cesarean section is to be preferred, unless there are signs of infection, when hebotomy is the method of choice.—*L'Obstétrique*, October, 1908.

Causes of Mortality of Cancer of the Uterus and Its Treatment of Hysterectomy.—F. Jayle states that localized cancer of the uterus may always be cured by a wide removal. It is rarely observed because of the belief of women and of physicians that hemorrhage is natural at the menopause, causing the patients to go to the surgeon too late. The best prophylactic measure is for women over thirty-five years of age to submit to an examination every three months. Cancer that has been propagated from the uterus to other tissues in a certain proportion of cases gives a preservation of life that is of value and that may last for a long time. The periuterine induration may be inflammatory, especially in infected cancers, and operation should be undertaken whenever there is any hope of obtaining a cure. In almost all cases extirpation should be done by the abdominal route, and should include the removal of the adnexa, perinterine cellular tissue, upper part of the vagina, and iliac ganglia.—*La Presse Médicale*, December 2, 1908.

Nitrogenous Hyperalimentation.—L. Zola says that it is not difficult to define hyperalimentation and hypoalimentation when they are extreme; when, however, we have nearly reached their confines it is difficult to tell when sufficiency ends and repletion begins with regard to nitrogenous substances. It is possible to maintain a comparative well being on not more than one-half the amount prescribed by Voit, that is with about fifty grams. If the organism introduces more than enough nitrogen to repair the cellular loss of daily life the excess of nitrogen is deposited under the form of proteid substances. A large part is rapidly re-eliminated by the liver and kidneys, giving them excessive work. Uric acid is the principal product. When the body must repair the ordinary wear of life or that of disease, or has to grow, a relative hyperalimentation with nitrogen is useful and necessary. It is not necessary and is even harmful in the healthy adult, because without being of any use to him it exposes him to immediate and remote dangers. Superalimentation with meats in tuberculosis is not a simple therapeutic measure, and should be superintended and watched over with the greatest care.—*La Riforma Medica*, November 23, 1908.

Pathogenesis of Hematuria During and After Purpuric Eruptions.—R. Del Vecchio describes a case of influenza with follicular tonsillitis in a girl of twelve years of age, followed by a symmetrical perpuric eruption of the lower extremities, and hematuria occurring in crises, each crisis of renal albuminuria being accompanied by a fresh eruption and gastro-enteralgia. The periods of hematuria then became less frequent. The general condition was at all times good. Frequent examinations of the urine showed a quantity of albumin always proportional to the amount of blood, a normal elimination of urea, constant presence of hyaline, granular and epithelial casts, and absence of neoplastic elements and tubercle bacilli. Specific gravity was 1011-1020, daily quantity 1300-1500 cubic centimeters. The author accounts for this condition by a disseminated vasomotor stasis of toxi-infective origin, due to a process analogous to that found in the disseminated cutaneous stasis and the purpuric eruption.—*La Riforma Medica*, October 10, 1908.

Digestive Troubles in Rickets.—A. B. Marfan discusses the digestive disorders found in rhachitic children. There may be a preceding gastro-enteritis with relapses and intervals of freedom from disease, or there may be dyspepsia with repeated vomiting, either condition preceding the enlargement of the bones. The form that occurs later, coincident with the bony enlargements, is a chronic dyspepsia, with variable appetite alternating with voracity. Flatulence is present and the large flaccid abdomen develops with elongation and true atony of the intestine. This condition is essentially chronic and lasts throughout the disease. The loss of weight is inconsiderable. There are cases in which there is no preceding gastrointestinal trouble. The author believes that the chief predisposing causes of rickets are improper feeding, heredity, and living in dark, damp, sunless surroundings. In a child thus predisposed there are several kinds of exciting causes: toxi-infective digestive troubles, hereditary syphilis, pyodermitis, broncho-pneumonia with relapses, and infectious diseases of children. All these operate to bring about rickets in the predisposed child.—*La Presse Médicale*, November 18, 1908.

Book Reviews.

Diseases of the Heart. By James Mackenzie, M.D., M.R.C.P. Oxford Medical Publications. London: H. Frowde, and Hodder and Stoughton, 1908.

All practitioners of medicine, and especially those particularly interested in cardiovascular pathology, will welcome eagerly this most interesting and novel treatise on diseases of the heart. The work is no text-book, and those who are looking for an ordinary guide to the physical diagnosis and treatment of heart troubles will be pleased with something more elementary. Those, however, who are more or less familiar with the modern methods of study of the circulation will find here a careful and most lucid presentation, and to those who know little or nothing of the recent advances in cardiodiagnosis and in the physiopathology of the heart the work will be as a revelation; they will find here a new science of absorbing interest, and one which promises to increase immensely our power over diseases of the heart and vessels. In the matter of diagnosis, for example, a study of the venous pulse, as seen in the jugulars, gives far more information regarding what is going on inside the cardiac chambers than does the radial pulse, which gives us knowledge only of the action of the left ventricle, and then only during the period that the aortic valves are open; yet it is within a very short time that the jugular pulse has been looked upon other than in the light of a curious but unimportant phenomenon.

The book opens with a discussion of the general principles underlying heart failure, and this is followed by a brief summary of the development, anatomy, and physiology of the heart and considerations on the general symptomatology and diagnosis of heart disease. The irregularities of cardiac rhythm are then discussed, and after this the muscular and valvular troubles, cardiac diseases, and the senile heart are described. Chapters on general prognosis and treatment end the body of the book. In the appendices are discussed the pulse in angina pectoris, the "nodal" rhythm, irregularities in cardiosclerosis, and the effects of digitalis on the heart. There is an excellent modern bibliography, and a full index completes the work. Dr. Mackenzie has written a great book—far and away, with the limitations above noted, the best work on the heart in existence to-day.

Quain's Elements of Anatomy. Editors, Edward Albert Schäfer, LL.D., Sc.D., F.R.S., Professor of Physiology and Histology in the University of Edinburgh; Johnson Symington, M.D., F.R.S., Professor of Anatomy in Queen's College, Belfast; Thomas Hastie Bryce, M.A., M.D., Lecturer in Anatomy, University of Glasgow. In Four Volumes. Vol. I, Embryology, by T. H. Bryce. Illustrated by more than 300 engravings, many of which are colored. Eleventh Edition. London, New York, Bombay, and Calcutta: Longmans, Green & Co., 1908.

This book, though the first volume in the series of four which will constitute the new edition of Quain's Anatomy, is in reality an independent treatise on Embryology, and is not a new edition, but actually a new book by a new author. This section in the former edition was written by Prof. Schäfer, but in the present one has been entrusted to Dr. Bryce, who has practically rewritten it, incorporating many additions made necessary by the advance in our knowledge of human embryology in the seventeen years since the tenth edition was issued. The work is divided into two parts dealing respectively with general embryology and with the development of the individual organs. The author is evidently thoroughly familiar with his subject, and possesses the happy faculty of imparting his knowledge to others in a very clear and readable style. In his descriptions he is aided by a large number of excellent illustrations, many of them original, well drawn and well printed. The work begins with a description of the somatic and sex cells, followed by a consideration of segmentation, the formation of the germinal layers, and the evolution of the embryo and its envelopes. There is some confusion here and the author does not clearly distinguish between human and comparative embryology; this is, however, often difficult, if not impossible, and is moreover not always necessary.

In the second section the development of the various systems and organs is treated of on the basis of the germinal layers from which they are derived, the order being: Skin, nervous system, eye, ear, and nose; alimentary canal, genitourinary system, suprarenal bodies, vascular system, lymphatics, and spleen; body cavity, muscles, and skeleton.

In the interest of economy of space, Dr. Bryce has omitted the bibliography which formerly closed each section. For the ordinary student this is a matter of no consequence, but it will perhaps be regarded as a serious omission by the more advanced student and specialist. On the whole, however, we think the author was wise in not burdening his pages with lists which could only be a copy from other works to which the specialist would have ready access. The multiplication of bibliographies is wasteful, for such lists are really necessary only in treatises on new subjects before there has been time for their publication in the Index Medicus and catalogues of the large libraries. To the student especially this excellent treatise on embryology can be confidently recommended.

General Surgery. A Presentation of the Scientific Principles upon which the Practice of Modern Surgery Is Based, by Ehrich Lexer, M.D., Professor of Surgery, University of Königsberg. American Edition edited by Arthur Dean Bevan, M.D., Professor and Head of the Department of Surgery, Rush Medical College in affiliation with the University of Chicago. An Authorized Translation of the Second German Edition by Dean Lewis, M.D., Assistant Professor of Surgery, Rush Medical College in affiliation with the University of Chicago. With 449 illustrations in the text, partly in color and two colored plates. New York and London: D. Appleton & Co., 1908.

Lexer's Surgery is well known in Germany, where it is recognized as perhaps the best of the modern works on general surgery in that country, and we doubt not this translation will enjoy considerable popularity here, though there is no lack of works in this branch in the English language. The book is not a mere translation, for much has been added to the original by the editor. There is a chapter on Blastomycosis by Ormsby, and in the appendix are an abstract of Crile's work on direct transfusion of blood and a brief note by Rosenow on bacterial therapy; Rosenow also contributes a chapter on surgical hematology, and the editor has made numerous changes and additions throughout. These additions, though plentiful, are judiciously made, and greatly increase the value of the work to the American reader. There are additions also among the illustrations, the subjects of these being from the editor's clinic.

The translation is excellently done, and is free from all teutonisms. Curiously, a paragraph on the diagnostic value of the presence of spirochetes in congenital syphilis is left untranslated. The volume is neatly printed on only moderately calendered paper, and is well bound. It is a commendable introduction to the science of surgery, and practitioners, as well as students, may read it with profit.

A Manual of Natural Therapy. By Thomas D. Luke, M.D., F.R.C.S. (Edin.), Lecturer at the University of Edinburgh; formerly Physician at Smedley's Hydropathic and Sanatorium, Matlock; Assistant Visiting Physician, Smedley's Memorial Hospital; Physician to Hazelwood Hydropathic Establishment, Grange-over-Sands, etc. Fellow of the British Balneological Society; Member of the Electro-Therapeutic (Royal Society of Medicine). With 30 plates and 125 illustrations, many of which are original. New York: William Wood & Company, 1908.

This volume deals with the most useful of the modern methods of physiological therapeutics. The author's intentions are not to go into infinite detail of any special method, but to portray the chief points and principles in the use of several. The first section deals with hydrotherapy, and in it may be found valuable details of technique carefully given, together with the limitations and dangers which should be known and not ignored. Sections II and III deal with Heat, Light, Massage, and Rest, all valuable means to restore health and too little understood. A specially good section on Electricity describes Galvanism, Faradism, Sinusoidal Currents, Electric Baths, Static Electricity, and High-Frequency Currents. To those contemplating the use of these methods, many valuable hints are offered. The concluding sections deal with Diet and the Modern "Cure."

Throughout the work the author shows his personal knowledge of the procedures he describes. He also understands their uses and limitations, so that the book may be considered a safe, concise, introductory guide to the use of physiological therapeutics.

A final word in approbation of the many well-selected pictures is in order. These plates are time-saving to the reader, and make clear at a glance what would take a much longer time to understand from the text. It also obviates mistakes in technique, a common cause for the neglect of these methods, since results are not good where the mode of application is not thoroughly understood by the physician in charge; and each year the doctor is entering further into this field, too long left to the care of attendants and empirics.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 28, 1908.

Dr. J. Riddle Goffe in the Chair.

Resolution on the Death of Dr. McCosh.—Dr. Sturgis moved that the President appoint a committee of three to draw up proper resolutions regarding the death of Dr. Andrew J. McCosh. This was unanimously carried. Dr. Goffe said he would appoint this committee later.

Exhibition of an Improved Gas Ether Inhaler.—Dr. James Taylor Gwathmey made this exhibition. The improvements consisted mainly in a much larger reservoir and larger valves than in those he had previously used.

Treatment of the Opium Habit.—Dr. W. Duncan Silkworth said that when the governments of the world were considering the advisability of the complete suppression of the opium and morphine trade, and our own country was making every effort to solve this great problem, a striking contrast was offered by the seeming apathy and indifference of the medical profession to the growing prevalence of the drug habit. If they were to delegate to the government the task of suppressing the growth of the drug habit, they should be deeply interested in caring for those who, now numbering among the thousands, seemingly depended on the drug for their daily existence. As the habit of using morphine was very often introduced, directly or indirectly, through the medium of the physician's prescription, it would seem that the responsibility of caring for those addicted to the drug rested primarily with the medical profession. A general classification of the habitué should be of some assistance to the physician; for example, first, the morphinomaniac; second, those surrounded and pampered by friends in their own homes; third, those who were either dependent on their own efforts to live, or possessed some responsibility which they could not shirk, and who often continued the use of the drug for years without very disastrous results; fourth, a class among whom the use of the drug formed a part of the social life. The value of such a classification could be recognized in determining the possibilities of successful treatment and the method to be pursued in each case. With the first three, the morphine habit was acquired generally to relieve a discomfort, and not from wrong motives. Fear and distrust follow after, induced largely by the attitude of the public and the profession. On all sides they were confronted with pessimistic views of their ultimate recovery. Dr. Silkworth believed that every physician of integrity and sound judgment had the ability to treat successfully any normal case of drug addiction that came to him. One such physician in every community willing to devote his time to the subject would actually solve the problem. The physician must have the entire confidence of the patient and keep it. This he could not emphasize too strongly. Again he must exert to the utmost encouragement, tact, sympathy, and perseverance. The patient must be imbued with the idea that the physician had confidence in him. The withdrawal of the drug must be undertaken according to the judgment of the physician in each individual case, the tendency being to hurry and to overmedicate the patient for the purpose of relieving unavoidable or natural symptoms.

The Pathology of Suppurative Otitis Media.—Dr. H. O. Reik of Baltimore said that suppurative otitis media was an infectious disease caused by any one of the pyogenic microorganisms which might gain entrance to the tympanic cavity and which found there suitable soil upon which to feed and proliferate. It was always an infection, but had no specific causative germ. Under ordinary circumstances the middle ear was an aseptic cavity, its sterility being due to the fact that nature had established a guard against the admission of germs and, to a lesser degree, to the presence of a mildly antiseptic secretion from the mucous membrane lining the tympanum. The epithelium of the tympanopharyngeal tube was of the ciliated variety and the cilia waved towards the pharynx, thus obstructing the progress of invading bacteria. Added to this physiological process the force of an outpouring secretion from the irritated mucous membrane, which naturally sought exit by this channel, and one had a fairly efficient protective power. Should these sentinels be passed, the germs gaining entrance to the tympanum had still to do battle with the bactericidal properties of the mucous membrane and its secretions. Any injury to the lining membrane of the tube or any disease which impaired the function of the cilia of that membrane favored the attacking foe; likewise, invasion by a host of bacteria, or by specially virulent microorganisms, might overcome all protective powers and establish a local disease. Irritating substances might be conveyed from the pharynx to the tympanic cavity by an act of forcible inflation of the tympanopharyngeal tube. A perforating injury of the tympanic membrane might be the means of introducing pyogenic microorganisms, or they might gain admission by what was known as the hematogenous route. Equally important elements in the etiology and pathology of the affection were the predisposing causes. First among these should be considered the effect of exposure to cold, producing disturbances of the normal vasomotor balance within the tympanum. Depleting diatheses favored infection through weakening the resistant powers. More important than systemic debility or simple exposure were the common affections of the nose and throat. Dr. Reik then pointed out the highly important rôle that nasopharyngeal disease played both in the causation and continuance of suppurative otitis media. Not only did adenoids and diseased tonsils predispose the ear to attacks of inflammation, but their removal was often absolutely essential in the treatment of aural disease. Repeated attacks of rhinitis, pharyngitis, or tonsillitis, or the existence of abnormal developments in the nose or throat, with their attendant conditions of persistent congestion of the tympanopharyngeal tube and tympanum, were most favorable to an infection of the middle ear. Just the conditions most conducive to the growth and activity of bacteria were obtained in this way, namely, a lowered resistance of the tissue cells and a serous pabulum in a protected chamber that was heated to the proper degree of temperature. Ulceration was probably constantly associated with suppurative otitis media. The extent of the ulcerative process varied considerably. The most frequent result of ulcerative inflammation in the tympanum was erosion of the membrana vibrans. This portion of the external wall of the tympanum, the so-called drum head, was the weakest of all and the only one that could give way before the pressure of an accumulating exudate. But spontaneous rupture of the drum head was not the invariable result; this fact was deserving of the greatest consideration when dealing with middle-ear inflammations in young children; the diminution of pressure within the tympanum was sometimes possible through the escape of excretions, by way of the tympanopharyngeal tube into the nasopharynx. Many of the cases of obscure febrile affections in infancy and early childhood were really due to undetected middle-ear inflammations and the diagnosis might have been very easy had any examination of the ears been made. While in the vast majority of all cases of suppurative otitis media the pathological changes were confined to the tympanum it must be remembered that the most serious aspect of the disease had to do with the possible invasion of important neighboring structures. Dr. Reik presented drawings of sectioned temporal bones and frozen sections of the head which explained very graphically and

impressively certain anatomical factors, showing why some cases tended to become the seat of chronic purulent inflammation and why others invited the invading bacteria to travel beyond the confines of the middle ear.

The Non-operative Treatment of Suppurative Otitis Media.—Dr. EDMUND PRINCE FOWLER read this paper. He believed that if there existed the slightest obstruction to nasal respiration or to a free ventilation of the Eustachian tube, it was surely a crime to neglect the removal of conditions which were so prone to be etiological factors in the causation of ear disease. The most effective measures to be employed during the onset of an otitis were those brought to bear on the nasopharyngeal condition and on the Eustachian tube. He always administered calomel, put the patient to bed on a fluid diet, avoided all stimulants, and secured as perfect rest for the body and auditory apparatus as was possible. Dover's powder and hot drinks were serviceable to produce perspiration and to diminish the fever often present in adults and almost without fail in children. A properly adjusted cold compress about the throat seemed to be of real service in relieving the throat and nose inflammations and if this was supplemented by an overlying constriction of elastic webbing, the patient usually experienced a sense of rest and well-being that was difficult to explain. Various local applications were of use if there were definite indications for their employment, but by gargling little was gained. During the past year he said he had seen several acute inflammations of the ear run their course without rupture of the drum, and in all of these he had made use of a new method of treatment. He referred to what he called suction-bell irrigation, which was applied to the ear every two hours, and when a hot solution was used therewith, it seemed to exert a beneficent action not only upon the middle ear, but also reflexly on the Eustachian tube, and the pain was usually relieved. As soon as the tube was able to take care of the exudate he instituted gentle inflation. From first to last the tympanic membrane must be carefully watched, for it was the appearance of this membrane that gave valuable guides to diagnosis and treatment. If the pain and tenderness did not subside it was probable that the inflammatory reaction was beyond control and that the tension within the auditory apparatus must be relieved by a free incision of the drum membrane. The drum should be freely incised if there was pus retention in the middle ear or adjacent cavities. Unless there were contraindications he preferred to do the operation with the patient under the influence of gas. If a local anesthetic was to be used he preferred the following mixture: Cocaine, two drams; carbolic acid (95 per cent.), one dram; menthol, one dram. Ten minims was dropped into the canal and allowed to remain five or ten minutes; this should be followed by the instillation of alcohol and drying the canal. The frequent removal of the discharge was usually necessary for cleanliness and comfort. In some cases hydrogen peroxide might be useful to loosen mechanically an inspissated discharge, but care should be used not to cause damage by the explosive action of this substance. If troublesome granulations occurred about the perforation, or in the canal or middle ear, they should be removed by caustics. If, with the cessation of the discharge the perforation healed, he stopped gradually all irrigations and instituted daily politzerization, or simultaneous inflation of the middle ear and external auditory canal. In a series of over one hundred cases with chronic running ears he obtained positive reactions to the tests of Calmette or von Pirquet with but few exceptions. Whereas in actute cases the percentage was small and as a rule the reaction was obtained only in those who gave tuberculous histories. Antiseptic solutions seemed to exercise a beneficial influence on the purulent processes. Dr. Fowler usually used boric acid and salt solution, or bichloride of mercury in strengths from 1-1,000 to 1-10,000. Solutions for introduction into the ear should never be cold.

Operative Treatment of Purulent Otitis Media.—Dr. WENDELL C. PHILLIPS read this paper. He said that the bulging of the drum membrane, intense pain, and fever constituted a syndrome of sufficient import to warrant paracentesis of the drum membrane. The drum membrane should be opened as soon as the diagnosis of purulent tympanitis became positive. The incision should be clean cut and the patient should remain in bed until all the acute symptoms had subsided. A simple method of removing large polyps was by means of a small aural snare; this should be followed by cauterizing the stump. Ossiculectomy was employed as a means of curing chronic purulent otitis media by the removal of diseased tissue and the promotion of drainage and of rendering the tympanic walls more accessible to local treatment. ecrosis of bony areas which were closely related to vital structures, the prolonged and constant danger of serious labyrinthine and intracranial complications, and loss of hearing were deleterious and dangerous results which followed an acute mastoiditis and which a mastoid operation quickly terminated. The radical mastoid operation was performed for the cure of chronic purulent otitis media.

Dr. EDWARD B. DENCH wished to emphasize more fully what had been said regarding the presence of fever in cases of acute otitis media; frequently in young children this was the only symptom present. It was therefore very important that the ears should be examined carefully in every case of unexplained fever. He protested against performing myringotomy under local anesthesia, because general anesthesia was so much more efficient. It was not always necessary to wait for bulging of the membrana tympani before doing this operation: when there was pain present with a little redness, he incised the drum. He endorsed what was said regarding ossiculectomy; in a small proportion of cases this operation had a place, but it was simply a preliminary stage to other operations. In reference to the simple mastoid operation fever in children was one of the best indications for its performance. A purulent ear with high temperature was an indication of great value. As to the radical mastoid operation, he disagreed with what had been said regarding the effects upon the hearing, for he had performed this operation and hearing had been improved in some cases, but not in all.

Dr. JAMES F. MCKERNON said he did not believe that granulations followed an acute otitis media unless there were dead bone present. He objected to the term paracentesis; it was a term that should be relegated to the past. It was far better to speak of an incision of the drum membrane. He echoed what was said regarding the removal of polypoid growths in cases of chronic otitis media; it was a dangerous procedure to remove those granulations in the canal, and particularly so if the patient was not immediately placed in bed and watched carefully. A blood count was to him a help as showing a low grade of vitality. In all but possibly one case the hearing had been diminished after the complete radical mastoid operation.

Dr. SAMUEL J. KOPETZKY did not think it was conservative surgery to incise the drum membrane when there was no pus present: such an incision would make infection more liable to happen. He said he could not emphasize too strongly the dangers of the postnasal douche; this was one of the great causes of mastoid suppuration. Chronicity in some of these cases was not a matter of time; many cases were chronic from the start. Dr. Fowler's douche would rob the observer of a certain number of symptoms in some cases; by its suction action it relieved the intramastoid process; it would eliminate certain symptoms, but the process would go on nevertheless. Causing a sudden cessation of pain was to deprive the surgeon of one of the most valuable symptoms. He was sceptical

regarding the absorption of pus in the middle ear when the process had reached a state where the drum membrane bulged. He said that he believed inflation of the ear when there was pus present was a more or less dangerous procedure.

Dr. Joseph A. Kenefick confined his remarks to the occurrence of ear disease in children, and said he wished to emphasize the importance of the influence of adenoid vegetations upon the causation of otitis media. He believed three forms should be considered, viz., those cases in which the breathing spaces, as well as the tubes, were occluded; those cases in which the breathing spaces were occluded and the tubes open; and those cases in which the fossa of Rosenmueller was occluded. The best treatment of acute mastoiditis was the removal of adenoid growths from the fossa of Rosenmueller before the otitis media began. In children he would not use Fowler's douche. With regard to the incision of the drum membrane, he said that it should be remembered that in children this membrane was at an angle of forty-five degrees when the child was looking at the ground; therefore, he went in close to the bottom of the floor and made his incision from below upwards.

Dr. Robert C. Myles said he had had from ten to fifteen years' experience in operations upon the mastoid on the cadaver and believed that he was quite an expert at it, but the men of modern times should consider the mastoid operation more from the clinical and pathological standpoint, as well as from the surgical. An abscess there should be considered as as abscess in other parts of the body and treated as such by free drainage and free ventilation.

Dr. Hill did not believe that the operation of ossiculectomy would cure the cases referred to; the operation he believed to be indicated when the bones were keeping up the chronic otorrhea and interfering with drainage. In certain cases this operation had its place. The radical operation should be performed in young children as in adults; age made no difference.

Dr. Reik said that the otologist should convey to the family physician certain definite points, and three of these he wished those present to take home with them: (1) Suppurative otitis media was a dangerous disease; (2) if a suppurating disease was neglected, it might lead to serious complications; (3) one should realize that practically all cases of suppurative otitis media, whether they had been in existence forty days or forty years, could be cured. He said that sixty per cent. of the number of abscesses about the ears originated from neglected middle-ear disease. Lateral sinus thrombosis cases, with the exception of a very few, started from neglected cases of suppurating otitis media. A large number of the cases of meningitis, and practically all the cases of extradural abscesses, originated in the same way. In the treatment of otitis media he preferred using a solution of formalin, believing it to be superior to boracic acid solutions. One-half a dram of formalin to the pint would give a solution of the gas of the strength of 1-600, and this was stronger than a 1-5,000 solution of bichloride of mercury from a bactericidal standpoint. He urged the observance of caution in the use of peroxide of hydrogen as a cleansing means, for he said he had seen a number of cases which went on to the development of a mastoiditis as the result of the careless use of this agent.

Dr. Fowler said that he meant to imply in his paper that polyps and granulations should be removed by caustics. He was of the opinion that the use of the snare in the middle ear was dangerous. With regard to the nasal douche, however, he believed its dangers had been exaggerated. Thousands of people used the nasal douche every day, and yet there were very few who ever suffered from middle-ear disease in consequence.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, December 1, 1908.

The President, Dr. B. Sachs, in the Chair.

A Case of Otitic Brain Abscess Operated on Thirteen Years Ago.—Dr. Gorham Bacon presented this patient, a man of forty, who was operated on by Dr. Bacon thirteen years ago for a temporosphenoidal abscess of the left side. At that time he gave a history of chronic otorrhea of sixteen years' standing. Four days prior to coming under Dr. Bacon's observation he complained of a severe pain in the left ear, with profuse discharge, and it was said that during this time he acted rather queerly. On December 5, 1895 (four days after the onset of his pain), he had a general convulsion lasting twenty minutes, with loss of consciousness, violent twitching, and frothing at the mouth. Prior to this he had never had any convulsive seizures. The patient was removed to the New York Eye and Ear Infirmary and was operated on first for mastoid trouble. Within forty-eight hours he developed an amnesic aphasia which was quite marked. On the ninth day after the operation he had a severe chill during the night, with profuse perspiration and severe headache. His symptoms at this time were very suggestive of sinus thrombosis. The skull was thereupon opened in the left temporal region and an ounce and a half of pus was evacuated from an abscess in the temporosphenoidal lobe. Shortly after the operation he had several convulsive attacks. His aphasia gradually improved, and on January 29, 1896, had entirely disappeared. During the thirteen years that had elapsed since the operation, this patient had had twenty-two convulsive attacks. The last one, which occurred in April, 1906, as well as the one occurring two weeks prior to that time, were very mild. The attacks were occurring at gradually increasing intervals, and were apt to come on after severe fatigue. The patient had been taking bromides irregularly.

Dr. E. Gruening, who was present and assisted Dr. Bacon at the operation, said he was particularly struck by the aphasia, as this was one of the first cases in which he had observed that symptom. The patient was able to describe objects that were shown him and he knew their use, but he could not name them. Since that time, Dr. Gruening said, he had successfully operated on five cases of temporosphenoidal abscess, and four of these he had been able to keep track of. In one of them, a child of five years, there were convulsive seizures accompanied by a leakage of cerebrospinal fluid from the ear. The child improved after spinal puncture. The four patients whom he had been able to follow had recovered completely and had had no epileptic seizures.

Dr. E. B. Dench referred to a case of temporosphenoidal abscess upon which he had operated four years ago. That patient, who was now in Cuba, had had two epileptic seizures; both, it seems, occurred after violent exercise about a year after the operation. He had now been free from convulsions for over eighteen months.

Dr. Edward D. Fisher thought it rather unusual that this patient should have suffered from amnesic aphasia instead of auditory aphasia, which we would expect to find in such a case.

Dr. Gruening said that this was the usual form of aphasia that was met with in abscesses of the temporosphenoidal lobe on the left side. In fact, instead of being unusual, it was pathognomonic of abscess in this location.

Dr. William M. Leszynsky said that several years ago he saw a patient in whom he made the diagnosis of otitic brain abscess. This patient had had a number of epileptic attacks. While being prepared for operation, she died suddenly from rupture of the abscess into the ventricles. At autopsy it was found that the abscess had involved the motor cortex as well as the temporosphenoidal lobe.

Adequate Methods of Drainage, the Essential Step in the Successful Surgery of Otitic Brain Abscess.—Dr. F. Whiting read this paper. (See page 133.)

The Common and Uncommon Localization of Otitic Brain Abscess, as Illustrated by Two Cases, with Recovery.—By Drs. B. Sachs and A. A. Berg. (See page 129.)

The Critical and Anatomical Manifestations of Otitic Brain Abscess.—Dr. Alfred Wiener read this paper. (See page 137.)

Dr. Gorham Bacon said he was fully in accord with the plan of treatment outlined by Dr. Whiting, and he had little to add to what had been said. He agreed with Dr. Wiener that abscess in the temporosphenoidal lobe was more frequent than in the cerebellum, and he recalled one instance which was on record where he had found an abscess in both locations in the same patient. The diagnosis of temporosphenoidal abscess was at times extremely difficult. Pain was the most constant symptom, and usually we obtained a history of chronic purulent otitis media.

Dr. Gruening said the symptom of optic aphasia in these cases had been known to otologists for a long time. Dr. Wiener stated that most of these abscesses were located near the diseased bone, but that in a small percentage of cases they were located at some distance from the bone and apparently separated from it by normal brain tissue. Personally, he did not believe that this intervening brain tissue, through which the infection had been carried by the lymphatics and vessels, was entirely healthy. For drainage material he preferred gauze, and he was opposed to irrigation. He had never found it necessary to use the encephaloscope, and was afraid that it might be the means of producing a false passage.

Dr. James F. McKernon said he had found the optic aphasia a prominent symptom in all of his left-sided cases of otitic brain abscess. In dealing with a brain abscess with thickened walls and containing a large amount of detritus, he saw no objection to the employment of a gentle, warm irrigation. It was certainly less harmful than curetting. In addition to four successful cases of the chronic type in which he had irrigated, he had also resorted to it in two cases of acute onset, one following the radical Stacke operation and the other after the opening of the mastoid and sinus. He had now given up irrigation in the acute cases, and simply mopped out the cavity with a bit of sterile gauze. In discussing the value of blood examination in the diagnosis of brain abscess, Dr. McKernon said that in one case of suspected abscess of the chronic variety, the differential blood count gave little or no information, because there was but little absorption taking place. The leucocytosis was about 12,000, with a polymorphonuclear percentage of forty-five. Upon operation he found an abscess at the posterior tip of the temporosphenoidal lobe, and evacuated about two ounces of pus. In another case the polymorphonuclears were ninety-four per cent. and the leucocyte count 34,000, which confirmed the diagnosis. The blood count was a valuable measure in differentiating between the acute and chronic type of abscess. The speaker said that he had discarded the use of the rubber tube a number of years ago as a mean of drainage, and now used either iodoform or plain gauze rolled up in the shape of a pencil.

Dr. E. B. Dench said he had operated in eighteen cases of otitic brain abscess, twelve of the temporosphenoidal type and six of the cerebellar. Of the former, six patients had died, five had recovered, and one was still under treatment. Of the cerebellar cases, five patients had died and one had recovered. Among his acute cases, some had shown an increase in the polymorphonuclears to above eighty per cent., yet that was not the invariable rule. In the chronic cases, the polymorphonuclear percentage was not usually very high. Dr. Dench said he agreed with what Dr. Gruening had said in regard to the encephaloscope. He could not appreciate how the educated finger could do as much harm as the uneducated encephaloscope. Ballance, in his operative work, used the finger regularly to gain access to the abscess cavity. Personally, Dr. Dench said, he employed two rather long retractors by which the brain substance was elevated, and this gave a very good view of the interior of the abscess cavity—better, he thought, than the encephaloscope—and there was less danger of traumatism.

Dr. W. Sohier Bryant said the spread of infection from the ear to the brain was accomplished in four ways: (*a*) Through the tegmen tympani into the middle fossæ; (*b*) through the internal auditory meatus and aqueducts into the posterior fossæ; (*c*) through the inner table covering the sigmoid groove over the sinus into the posterior fossa; (*d*) the infection in one fossa may spread into the next. All varieties of brain abscesses were of infectious origin. They occurred in all gradations, from an encapsulated abscess with a distinct pyogenic membrane and a minute connection with the original source of infection, to the other extreme—a diffuse softening; a mere enlargement of the original infection. After discussing in detail the diagnosis of otitic brain abscess, Dr. Bryant said the diagnosis was positive when focal brain symptoms occurred with a peripheral infection. A blood count was useful to determine the presence of active infection and the resistance offered to it by the patient, but it was of no value in locating the infection. Treatment was operative, and of two kinds: (1) Peripheral exploratory operations to confirm the diagnosis and to locate the abscess; (2) central operation for evacuation and drainage after the abscess had been located. It was best to follow the path of infection in planning the location of drainage. An operation should be undertaken the moment the diagnosis was made. An exploratory operation for brain abscess should be done as soon as indications of mastoiditis, sinus thrombosis or meningitis were present. Dr. Bryant said that during the past two years he had had eight cases of brain abscess, three cerebral and five of the cerebral and cerebellar type combined, with fifty per cent. of recoveries after operation. All the cases which were fatal were treated under special disadvantages, either from complications, lack of opsonic resistance, or delayed operation.

Dr. Joseph Fraenkel said that to the neurologist these cases of otitic brain abscess were comparatively rare. Personally, he had seen perhaps four or five, and he would limit himself to a discussion of the optic aphasia, to which several of the speakers had referred. Marie had recently shaken our old-time conception of aphasia, and to-night, the speaker said, he had received another shock along that line. What the otologists had described as optic aphasia was better known to neurologists as anomia, which was the loss of power to give objects their correct names. This did not, in his opinion, constitute an optic aphasia. In a case of this kind that was under the observation of Dr. Charles L. Dana and himself, the autopsy showed a minute lesion in the temporosphenoidal lobe. A true optic aphasia would point to a lesion in the occipital lobe or commissure.

Dr. J. Ramsay Hunt said the more he saw of otitic brain abscess the more pessimistic he became regarding the difficulties that surrounded not only their diagnosis, but their treatment. During the past eight years he had seen fifteen cases; all of the patients were operated on and all of them died. The operations were done in various hospitals throughout the city, and these unfavorable statistics could not be laid at the door of any one surgeon or group of surgeons. All were cases of cerebral abscess, and not extradural; of the latter, he had seen several end in recovery.

Dr. Fisher said that in dealing with otitic brain abscess,

or even suspected abscess, he was in favor of an early exploratory operation, preferably by a surgeon specially qualified in that field.

Dr. William M. Leszynsky said that during ten years' experience as consulting neurologist to the Manhattan Eye and Ear Hospital he saw quite a number of these cases, which he thought were less frequent now than formerly. He said that the experienced neurologist could often be of much assistance to the otologist during the earlier stages of otitic brain abscess, before the symptoms had become so unmistakable that any tyro could make the diagnosis. He recalled one case, seen several times in consultation, in which the otologist could not be convinced that a cerebellar abscess was present until it was shown to him at the autopsy. No mention has been made of one of the dangers attached to cerebellar abscess. Cases were on record when at the moment such an abscess was punctured, death occurred suddenly from respiratory paralysis. Such an instance had occurred under his observation. In view of that fact, it seemed logical to infer that in cases of brain abscess attended by sudden death from respiratory failure, the lesion was located in the cerebellum rather than in the temporosphenoidal lobe. Neurologists had long been familiar with the type of aphasia, which was of value in the recognition of otitic temporosphenoidal abscess when it was present. Most of the abscesses, however, did not occur on the left side, and it was invariably absent when the abscess occurred on the right side unless the patient was left-handed.

Dr. Felix Cohn said that in obscure cases of otitic brain abscess, a blood count should never be neglected, as it might aid in differentiating the condition from various forms of meningitis. The speaker reported a case of cerebellar abscess in which the condition of the increased reflexes led to the correct diagnosis.

Dr. Whiting, in closing, speaking of the encephaloscope, said it was simply a question of using the instrument with which one was familiar. It was an instrument which, with a very moderate amount of practice, gave a remarkably clear view of the abscess cavity, and could be used with great precision.

Dr. Berg, in closing, said he was inclined to agree with those who preferred rubber tissue to gauze in the drainage of an acute brain abscess. For drainage of a chronic, thick-walled abscess, some form of tube drain must be used, for when gauze became saturated it no longer acted as a drain, but as a tampon blocking up the pus in the cavity. In cases where drainage was really demanded, we could not rely on gauze; we had to resort to a tube of some material.

The President, Dr. Sachs, said that a common error made by surgeons and otologists was that they were inclined to attempt a brain operation through relatively small openings. If there was one factor that would lead to better results in brain surgery it was to do the operations through a large osteoplastic flap. The symptoms of sensory aphasia had not been carefully observed, and it was easily overlooked. The type of the aphasia in these cases depended on the location of the abscess.

Contribution to the Study of the Blood in Malaria.—Samuel Sereni has made experiments to ascertain whether the increased specific gravity of blood corpuscles containing malarial parasites has not something to do with their agglutination and deposit in certain organs. He has ascertained that an increase in specific gravity does exist. He considers it altogether probable that this condition favors the stagnation of the corpuscles containing parasites in the tissue meshes of certain organs, especially the brain, the normal corpuscles being found almost absent. Here on account of the small size of the capillaries, the circulatory resistance is great, and the degenerative changes of the endothelia are great. Stasis becomes marked and the circulation is so slow and imperfect that these heavy cells are deposited.—*Il Policlinico.*

Special Article.

THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.

By J. AUER, M.D.,
NEW YORK.
ASSOCIATE OF THE INSTITUTE.

Development of the Institute.[1]—In 1901 the enlightened philanthropy of Mr. John D. Rockefeller rendered possible the incorporation of the first institution in the country devoted entirely to research in medicine. The purpose of this Institute was to further medicine in its various branches by establishing laboratories and by awarding money grants to trained investigators in other laboratories. The government of the Institute was and is still vested in a Board of Directors formed of the following eminent medical men: William H. Welch, T. Mitchell Prudden, L. Emmett Holt, Christian A. Herter, Theobald Smith, Herman M. Biggs and Simon Flexner.

During the first three years after incorporation the Institute had no home of its own, and restricted itself to aiding investigators both here and abroad by money grants. At the end of the first year, however, it became evident to the Board that greater progress in research could be obtained if the larger part of the investigations were carried out in one place and under the general direction of one head. This conclusion led Mr. Rockefeller to place still larger means at the disposal of the Board for the realization of this idea. After careful deliberation the Board decided to locate the Institute in New York City, upon the East Side. Many months were spent studying the leading institutions abroad before the final plans of the Institute were completed and the erection of its permanent home begun. In order that productive work be not delayed during the necessarily long time which would elapse before its final quarters were ready for occupancy, the Institute Board leased a small building, formerly a private house, at the corner of Fiftieth Street and Lexington Avenue, and equipped it roughly for research in experimental pathology, physiology and chemistry. Work was begun in this building in October, 1904, with Dr. Simon Flexner as director of the laboratories. Though the facilities at the disposal of the small staff of nine workers[2] were necessarily inadequate, a number of investigations were completed during the two years that these temporary quarters were occupied.

Present State.—At present three buildings form the Institute: the main laboratory building, the animal house and the power house. They are located upon rising ground at Sixty-sixth Street and the East River and are surrounded by a large free space. The laboratory building stands at the head of East Sixty-sixth Street, facing west, and is connected with it by a broad driveway flanked by a footpath. This building is a fireproof structure of steel and yellowish-gray brick. Its simple façade shows five full stories and a basement which is half above ground.

The basement is subdivided into a number of rooms of various sizes which contain the machinery

[1] This section is largely based on Dr. L. Emmett Holt's address, delivered at the opening of the Institute laboratories and published in the Institute Studies, 1907, viii, p. 17.

[2] The original staff consisted of Drs. S. Flexner, S. J. Meltzer, E. L. Opie, H. Noguchi, J. E. Sweet, P. A. Levene, W. A. Beatty, H. S. Houghton, and J. Auer.

Fig. 1.—General View of the Building.

of the building and also the heavier laboratory apparatus, such as centrifuges, steam evaporation basins, shaking apparatus, etc. Two of the rooms serve as storage rooms for laboratory supplies. In addition a machinist's repair shop, the laundry and living quarters for the janitor, are located in the basement.

The first floor contains the administrative rooms, offices, the library and an assembly room. The library is formed of four rooms and occupies about

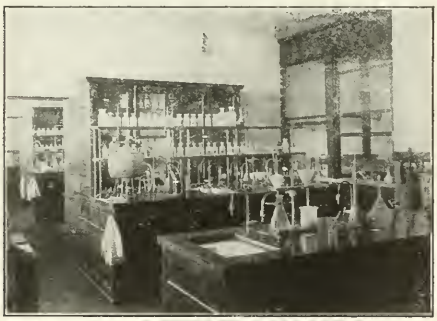

Fig. 2.—General Chemical Laboratory.

one-half of the floor space. The assembly room seats about one hundred people and is supplied with all connections necessary for demonstration purposes, including a stereopticon. This room is used for society meetings and for the weekly conferences of the Institute staff.

The entire second floor is occupied by the department of chemistry, and is divided into large and small rooms. The larger rooms are fitted out as general laboratories for a number of workers, while some of the smaller ones are used for special purposes; for example, the distillation room where alcohol and ether are redistilled, the hydrogen sulphide room, combustion room, etc. Recently a laboratory has been equipped for work in physical chemistry.

On the third floor are laboratories for experimental pathology, bacteriology and protozoology, all equipped with everything needful for general and special work. Besides these laboratory rooms, the private study of the Director is located at the north end of the floor. The south end of the floor is occupied by a suite of rooms designed especially for aseptic surgical work. This suite is composed of three rooms: in the first is a bathtub and a hot air drying chamber; here the animal is prepared for operation. In the second room are autoclaves and other steam connections for the sterilization of dressings and instruments. The inner room on the east side of the building is the operating room. There is also in connection with this suite, a fourth room paved with cement, which serves as an animal room. Here animals after operation and other procedures are conveniently kept under observation. As only small animals such as mice, rats, guinea-pigs, rabbits and monkeys are kept in this room, their presence is not noticeable in the main hall. These four rooms are connected by a corridor which also separates them from the main hall of the building.

Fig. 3.—Section of the Library and Reading Room.

The large general laboratory for bacteriology, on the western side of this floor, contains a built-in hot-air room whose temperature varies from 35 to 39 degrees C, depending upon the level at which this temperature is taken. This room serves for cultiva-

Fig. 4.—One of the Preparation Rooms—Bacteriological Clean ing Room.

tion and digestion experiments. In this room there is also a small shaking machine.

On the fourth floor are special laboratories for experimental pathology, for physiology and pharmacology; preparation rooms and a centrifuge room. The laboratories for pathology are formed by a series of four communicating rooms at the north end of the floor. They are equipped not only for ordinary pathological work but also for work in chemistry, including gas analysis.

The south end of the floor space is occupied by the department of physiology and pharmacology. The preparation rooms are two rooms on the western side where bacteriological media are made up; here also most of the hot-air and steam sterilization for bacteriological purposes are carried out. In an adjoining cement-floored room some of the smaller centrifuges are placed. These centrifuges are anchored on rubber and produce very little vibration when in action. There are two other laboratories upon this floor which are designed for individual workers.

All the laboratory rooms are equipped with hoods containing gas, electricity, hot and cold water, and vacuum connections. The hoods of the chemical floor, in addition, are supplied with steam.

The fifth floor contains the photographic studios, a special incubator room, a suite of two rooms for workers whose experiments demand night observation, a kitchen and dining room, and some unassigned and partly undivided floor space.

The photographic suite comprises five rooms fully equipped with cameras for ordinary and photomicrographic work. The dark room is entered through an S-shaped passage, with black walls—a great convenience as it obviates doors.

Each floor is provided with a large refrigerator which communicates with the main refrigeration plant in the basement. The refrigerators in the basement and in the kitchen are arranged for constant temperatures, while those on the second, third, and fourth floors are divided into three tiers of compartments so connected that each tier may be maintained at an independent temperature.

The various floors of the building including the roof communicate with each other by two stairways at the northern and southern ends of the building. There is also an electric elevator.

The water supply of the building is all filtered. Ventilation is secured by means of the "fan plenum" system.

All the various floors and departments are connected with each other by a house telephone, and on each floor is a telephone booth for city and long distance connections.

The roof really forms a sixth floor, for a considerable portion of the space has been covered by an iron house sheathed with copper. This house has been subdivided into a number of small rooms in which dogs are kept. Each of these rooms has a concrete floor and communicates with an outside, tiled runway. This runway is separated by heavy wire fences into as many compartments as there are rooms. Most of these dog rooms are located on the eastern side of the roof; only a few are on the western side. A separate room is utilized as a "dog kitchen"; there an attendant prepares the food for the animals.

At each end of this roof house is a suite of operating rooms similar to that on the third floor. The northern suite is at present used for work in experimental tuberculosis. In the southern suite, all the operations of experimental surgery are carried out. The operating room of this suite faces north, and its north wall and roof are constructed of glass so that sufficient light is secured for the most delicate work.

The animal house is a two story building of semi-fireproof construction and is connected with the main laboratory building by a covered passageway. The first floor contains stables for horses, sheep, and

Fig. 5.—Photographic Studio.

goats. A special room, whose temperature is kept constant, contains various species of monkeys and poisonous snakes. On the second floor are large, well-lighted spaces where cats, rabbits, guinea-pigs, and birds are housed. A small room provided with

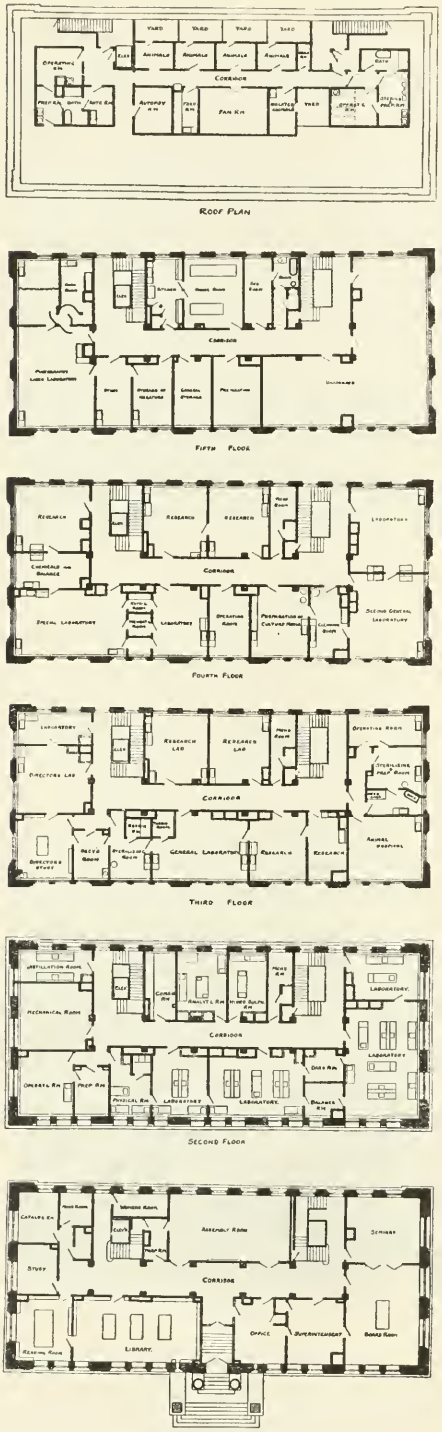

FIG. 6.—Floor Plans of the Institute.

a series of tanks is used for the storage of frogs. There is also a large loft for the storage of grain and hay.

The Institute has recently purchased a small farm of about one hundred acres in New Jersey. This farm serves a variety of purposes. Operated animals, horses which furnish the antimeningitis serum, are kept on this farm for various periods of time, especially during the hot summer months. Here also rabbits and guinea-pigs are bred. Moreover, part of the hay and grain used for the animals is furnished by this farm.

The power house contains three sixty-horse-power boilers which furnish the steam necessary for heating the buildings, for operating the pump, sterilizers, etc., etc. There is also a crematory for the destruction of carcasses, and a steam vat for their previous sterilization by steam, if infected.

These three buildings which have been briefly described above are the only ones at present completed. As yet there is no hospital in connection with the Institute, but this deficiency will be remedied shortly. At the time of writing this, ground has been broken for a hospital comprising two buildings, a main hospital of seven stories with a capacity for about fifty patients and a smaller two story building which is to be used as an isolation pavilion. These structures will be located south of the main laboratory building.

Organization.—As already stated the government of the Institute is vested in the Board of Directors, of which Dr. William H. Welch is president, Dr. L. Emmett Holt, secretary, and Dr. Christian A. Herter, treasurer. This body meets three times a year. Its immediate representative in the daily work of the Institute is the Director and Chief of the Laboratories, Dr. Simon Flexner.

As the work carried out in the Institute extends over a large and varied field, different departments have been created each with a more or less complete staff. This subdivision into departments is as yet incomplete, but at present there are three: experimental pathology, physiology and pharmacology, and chemistry. Of these the department of pathology is the most fully equipped and its work the most varied. Its staff is formed by Dr. Simon Flexner, head of the department, and Dr. E. L. Opie. With Dr. Flexner are associated Drs. Noguchi, Jobling, Carrel, Lewis, Wollstein, Lamar, and Terry. Dr. Opie is assisted by Miss Barker and Dr. Dochez.

The staff of the department of physiology and pharmacology is formed by Dr. S. J. Meltzer, head of the department, Drs. Auer, Joseph, and Shaklee.

In the department of chemistry the staff is formed by Dr. P. A. Levene, assisted by Drs. Heimrod, Van Slyke, Jacobs, Clarke, and Meyer. In addition there is a special laboratory for pathological chemistry under the direction of Dr. E. K. Dunham, assisted by Dr. Jacobson.

The photographic studios are in charge of Dr. Leaming.

The Institute staff is composed of workers holding various grades or titles which are conferred by the Board of Directors. These titles and their holders are as follows:

Member of the Institute: Drs. Simon Flexner, S. J. Meltzer, E. L. Opie, and P. A. Levene.

Associate Member of the Institute: This title is held at present by no one.

Associate of the Institute: Drs. Hideyo Noguchi, J. W. Jobling, A. Carrel, and J. Auer.

Assistant of the Institute: Drs. G. Heimrod, P. A.

Lewis, B. T. Terry, D. R. Joseph, D. D. Van Slyke, and W. A. Jacobs.

Fellow of the Institute: Drs. Martha Wollstein, R. Lamar, A. R. Dochez, G. M. Meyer, C. A. Jacobson, A. O. Shaklee, and Miss Bertha Barker.

Scholar of the Institute.

Student of the Institute.

Social Relations of the Institute Staff to Each Other.—During the early period of the Institute, especially during the occupancy of its temporary quarters on Fiftieth Street, there was opportunity for little intercourse between the workers in the different departments, and the three little communities of pathologists, physiologists, and chemists, though close neighbors, worked without really coming into daily contact with each other. To remedy this undesirable state of isolation two measures were introduced. First, a weekly conference was established at which designated members reported upon some contribution to their particular field or upon some completed investigation of their own. These reports were then open to an informal discussion by the Institute staff. The second and more effective measure to bring about personal con-

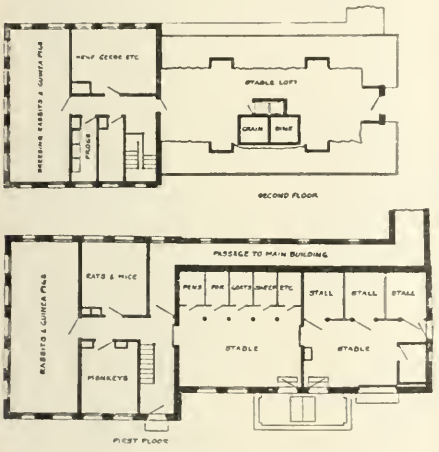

FIG. 7.—Floor Plans of Animal House.

tact between members of the staff was luncheon in common. This luncheon is served in the dining room of the Institute and here the workers now meet each other daily with mutual benefit.

There is also a well kept tennis court, located east of the main laboratory building, which gives opportunity for outdoor exercise to the Institute staff.

Character of the Problems Investigated.—As the title of the Institute indicates, the problems investigated by the Rockefeller Institute for Medical Research bear a close relation to and often are identical with the problems of medicine. Questions of purely scientific interest, which necessarily arise during the course of any investigation, are, however, not neglected. It is fully realized that all biological facts are valuable, but it is also realized that some biological problems are of greater immediate benefit to the art of medicine than others. These latter problems are the ones investigated chiefly by the Institute.

Some of the subjects at present being studied will illustrate the statement made above. The department of pathology, for example, is studying some of the problems of protective sera, of cancer, of tuberculosis, of trypanosomiasis, or anaphylaxis, of the transplantation of organs, of the bacterial flora of the intestine, and of the specific serum reactions in syphilis and other diseases, all of vital interest to medicine.

In the department of physiology and pharmacology attention is paid only to the functions of the animal organism, both normal and when experimentally modified by operation or by drugs. Some of the questions whose answers are being sought are the rôle which the inorganic salts of the body play in its economy; the motor-phenomena of the gastrointestinal canal; some aspects of the physiology of the heart; some of the problems of absorption; influence of mechanical agents upon ferment activity.

In the chemical department the subject of study is the identification of tissue fragments; the rôle which these tissue components play in the building-up of tissues, that is, their nutritive value in normal and abnormal conditions.

Scope of the Institute.—The investigations of the Institute are by no means limited to those carried out within the walls of the Institute proper. Throughout the United States and also in the medical centers of Europe there are numerous workers whose researches are supported by grants from the Institute. Nothing perhaps will illustrate the extent of this extra-mural aid more than the index of the last volume (VIII) of the "Studies of the Rockefeller Institute"; out of forty-five papers almost half were contributed by investigators who were not members of the resident staff of the Institute.[5]

Publications.—The published results of investigations which have been aided by grants or which have been carried out in the laboratories of the Institute are collected into volumes of about 300 pages. So far eight volumes of these "Studies from the Rockefeller Institute" have appeared. These "Studies" are sent to the leading laboratories, libraries, and learned societies both here and abroad.

In addition to the "Studies," the Rockefeller Institute publishes under the editorship of Dr. Simon Flexner and Dr. E. L. Opie, *The Journal of Experimental Medicine*. Its pages are not devoted exclusively to work conducted under the auspices of the Institute, but are open to any suitable article written in the English language.

[5]Detailed information regarding grants is contained in the "Circular of Information," which may be obtained from the clerk of the Institute.

Treponoma Pallidum in Syphilis.—Fouquet gives an account of the characteristics and life history of *spirochæta pallida* as far as it is at present known. It is noticeable that cultural experiments have so far failed in securing growths. The organism is probably a trypanosome. Its localizations are known in both hereditary and acquired syphilis. In the acquired variety it is present in the chancre deeply situated and frequent toward the periphery. In general it is found in the connective tissues along the blood-vessel lesions. It is carried by the lymphatics to the ganglia. It is found in the secondary roseola, and in cutaneous syphilides in the deepest layer of the rete Malpighii, here causing the disappearance of pigment such as is seen in 'eucoderma. It is rare in secondary visceral lesions, and in tertiary lesions, except as found along the blood-vessels. In hereditary syphilis it is found in the blood, placenta, both fetal and maternal, in the bullæ of pemphigus, nasal and buccal mucous membrane when affected, eyes, bones, liver, here being especially frequent, spleen, kidneys, pancreas, lungs, testicle, and ovaries. It accompanies the vessels of the nervous system. The action of mercurial treatment is to lessen the vitality and the reproduction of the parasite.—*Gazette des Hôpitaux.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 16, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	484	166
Diphtheria	394	47
Measles	462	16
Scarlet Fever	337	18
Smallpox	—	—
Varicella	163	—
Typhoid Fever	39	9
Whooping Cough	39	3
Cerebrospinal Meningitis	3	2
Malarial Fever	—	—
Totals	1921	261

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, for the week ending January 15, 1909:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS
California, Los Angeles	Dec. 19–26	1	
Oakland	Dec. 26–Jan. 2	4	
San Francisco	Dec. 19–26	8

LEUKEMIA IN ADVANCED LIFE.*

BY A. ALEXANDER SMITH, M.D.,

NEW YORK.

WHILE leukemia may occur in individuals at any age the two decades between 25 and 45 seem to be the favorite periods for its development. Although the disease is sufficiently often recognized to make it of comparatively little interest, very few cases have been reported after the age of 60. The very few cases occurring after 55 years of age have been almost all in men. Within a period of eighteen months I had the opportunity of seeing three cases in persons between the ages of 60 and 70, two of whom were women.

CASE I.—The first case was that of a lady, 70 years of age, a mother and a grandmother, living in her own home in the city, surrounded by luxury. She had spent the summer in the country, enjoying a fair degree of health. On her return to the city in October, 1903, she consulted her physician because of a persistent diarrhea and progressive exhaustion. His examination showed a moderate degree of fever, temperature 101.4° F., pulse between 90 and 100, moderate abdominal distention, a spleen very much enlarged and a quite decided degree of prostration.

A blood examination made October 24, 1903, showed: Reds, 4,280,000 per cm.; leucocytes, 320,000. Differential count: Polymorphonuclears, 1.9 per cent.; lymphocytes, 98.0 per cent.; basophiles, 0.1 per cent. Possibly the presence of diarrhea may have produced a concentration of the blood. The small lymphocytes predominated. There were no glandular enlargements.

A blood examination made December 17, 1903, showed: Reds, 4,250,000; hemoglobin, 75 per cent.; color index, .9×; leucocytes, 538,000; Differential count: Polymorphonuclear, 2.85 per cent.; lymphocytes, small, 95.68 per cent.; lymphocytes, large, 1.02 per cent.; transitionals, .30 per cent.; eosinophiles, .08 per cent.; basophiles, .07 per cent. I saw this lady with her physician in December, 1903, and could only confirm the very evident diagnosis. She died from exhaustion in between three and four months after I saw her.

CASE II.—The second case was that of a lady aged 64, and like the other living in her own home; she was surrounded by luxury and had been since her birth. She had spent the summer in the White Mountains and had returned to the city to her own home in November, 1905. During the latter part of her stay in the White Mountains she had suffered from a persistent diarrhea with some fever. The fever had not been measured as she had not consulted a physician. When I saw her in December, 1905, she had been under observation several weeks, having diarrhea, a temperature ranging from 100° to 102°, a pulse of 90 to 96, progressive exhaustion and an increasing pallor. When I saw her the pallor was a very noticeable symptom. I found her with a moderate degree of abdominal distention and a moderate enlargement of the spleen, not very tender on palpation. She was confined to the bed.

A blood examination showed: Reds, 4,112,000; hemoglobin, 65 per cent.; a few normoblasts present; leucocytes, 127,400; polymorphonuclears, 84 per cent.; lymphocytes, large, 3 per cent.; small, 4 per cent.; eosinophiles, 1 per cent.; basophiles, 1 per cent.; myelocytes, 7 per cent. She died in January, 1906, from progressive exhaustion. She had no renal or cardiac disease.

CASE III.—This patient was brought to me March 21, 1905, by his son, a physician, from northern Vermont, and was seen in my office. He was a judge of the Circuit Court of Vermont and was in his 60th year. He had the following history: Mother died of tuberculosis at the age of 47, father lived to 88 years of age. Five brothers all older than himself living and in good health. Habits always regular, has never been addicted to the use of alcoholic drinks; smokes rather immoderately, has four children living and in good health; had measles and mumps when a child; has always been able to attend to his duties and has never been ill in bed a day in his life until an attack of grippe four weeks ago. Digestion was always excellent except for the past three months he has had both gastric and intestinal flatulence. His normal weight up to 50 years of age was 115 pounds. His weight then gradually increased until one year ago he weighed 150. During the past few years has noticed a very slight dyspnea on exertion, but paid very little attention to it as he attributed it to advancing age.

In October, 1904, while going up a hill quite rapidly he had very marked dyspnea. His general health had seemed excellent until four weeks ago, when he had an attack of grippe and lost during this attack 15 pounds in weight. Attention has never been directed to abdominal swelling and he has had no abdominal pain. Appetite has always been good except during his attack of grippe, has never had any hemorrhages, has kept up his work regularly until this attack of grippe, and now again feels perfectly able to work and is anxious to do it. Since his attack of grippe he has refrained from doing any work at the earnest request of his family. His chief complaint was some dyspnea and palpitation of the heart on exertion and when the abdomen was distended. The physical examination revealed a heart considerably enlarged, the apex in the sixth intercostal space and a mitral regurgitant murmur. The liver was moderately enlarged; the spleen was very much enlarged, the lower border of it extending almost down to the crest of the ileum.

*Read at a meeting of the Practitioners' Society of New York, December 11, 1908.

The urinary examination showed a mild degree of chronic nephritis. The blood examination showed red cells, 3,418,000; hemoglobin, 85 per cent.; leucocytes, 440,000. Differential count: Polymorphonuclears, .18 per cent.; myelocytes, 65.4 per cent.; large lymphocytes, 5.5 per cent.; small lymphocytes, 10.5 per cent.; eosinophiles, .6 per cent. Very numerous nucleated red cells mostly megaloblasts, and no poikilocytes.

When the gravity of the illness was stated to the son he begged that his father be kept in ignorance of his serious condition, that he be allowed to return to his work, the son agreeing to take all the responsibility of such advice. He did return to his work and lived eight months being able to attend to his duties constantly up to within five weeks of his death, and then was obliged to cease because of increasing dyspnea.

The interest in these cases centers in the fact that they were all between 60 and 70, an age in which leukemia very rarely develops, and that two of them were women. Reports of cases in women at this age are more rare than of those in men. Two of the patients, the women, were born into luxury and always lived in luxury. A further fact of interest is that in the man, although he suffered from chronic cardiac and renal disease in addition to leukemia, he was able to perform his duties up to within five weeks of his death.

18 West Fifty-first Street.

SOME COMMON INJURIES OF THE ELBOW.

By JAMES P. WARBASSE, M.D.,

BROOKLYN, NEW YORK.

CHIEF SURGEON TO THE GERMAN HOSPITAL, ATTENDING SURGEON TO THE SENEY M. E. HOSPITAL.

The injuries to the elbow joint which demand the consideration of the surgeon are contusions, wounds, dislocations, and fractures. In this short discussion, it is not my intention to take up each of these conditions and systematically consider its surgical phases, but I shall wander away from the general path and briefly call attention to certain features of these injuries, the consideration of which may be of profit.

Contusions of the elbow joint are of interest because of the fact that if the contusion is not great enough to cause a fracture it usually amounts to very little. The three bony prominences—the two condyles and the olecranon—which surround the elbow, stand out so prominently that contusion of the joint structures or of the folds of synovial membrane are almost impossible. One or the other of these prominences may be struck, and the soft parts contused are only the skin and the underlying fascia. How very different this is from the analogous joint, the knee, in which the bony eminences have become rounded off and in which the patella, the analogue of the olecranon, offers no protection whatever against contusions of the joint structures. In fact, the synovial membrane of the knee is as much exposed to contusion through the patella as the elbow would be were there an ununited fracture of the olecranon. It is for these reasons that traumatic synovitis, so common in the knee, is so rare in the elbow joint.

There is one injury to this joint to which I desire to call attention and which I have never been able to find described. It may be designated as sprain of the radial flexors, and at first sight simulates fracture of the external condyle of the humerus. The injury is sustained by falling with the arm twisted under the body. Swelling about the outer side of the joint rapidly develops, but the characteristic symptom is a preternatural prominence of the supinator radii longus muscle. I have seen five cases of this condition, and in all of them, after determining that there was no fracture of the external condyle, the impression was present that the supinator longus originated from the humerus at a higher location than normally. If the elbow is held at a right angle the angle is obliterated by the muscle, the anterior border of which makes the hypothenuse of a triangle. The muscle looks to be in a state of strong contraction, but palpation shows that it is in a state of semirelaxation, still it seems to originate nearly as high as the middle third of the humerus and to pass down to the middle of the forearm. There is much tenderness and swelling. Motion of the joint is limited by pain in the region of the radial flexors in front of the external condyle. If the arm is put up with a snug bandage and carried at a right angle in a sling the deformity and pain disappear in a week, and in another week there is no sign of injury. The reason which I assign for this swelling and unnatural prominence of the supinator is a rupture of the external reflection of the deep fascia, which binds down this

group of muscles, and the swelling of the muscles incidental to the contusion. One of these cases I known to have been diagnosed by a competent man as fracture of the outer condyle.

When we come to the consideration of fractures

Fig. 3.—K. R. Separation of Lower Epiphysis of the Humerus; flexion at an acute angle; in plaster-of-Paris, better position.

of the condyles, which have had placed upon them the unfortunate designation of "fractures of the elbow," we will do well to bear in mind the centers of ossification of the lower end of the humerus. This is particularly important because these fractures are among the common injuries of childhood.

At birth the epiphysis is wholly cartilaginous below a transverse line passing through the lower part of the olecranon fossa. This line soon descends centrally to the lower edge of the fossa. About the middle of the second year the first center of ossification appears in the capitellum. About the tenth year this center has enlarged nearly to the trochlea, and an ossific center appears in each epicondyle. The diaphysis has grown down into the inner portion of the trochlea so that the lower epiphysis is a

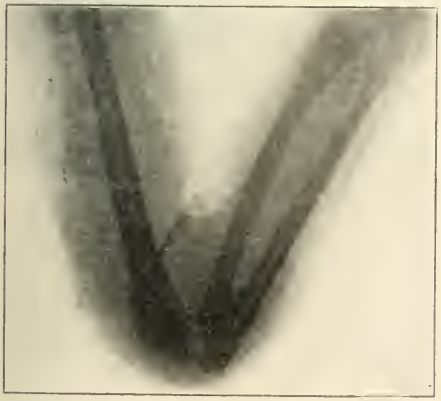

Fig. 4.—K. R. Separation of Lower Epiphysis of the Humerus; extreme flexion, perfect position. These first four figures show the changes of position produced in the same fracture by four different degrees of flexion.

boat-shaped cartilage with its hollow upwards. The capitellum unites with the epicondyle between the twelfth and fourteenth years. After this the last point of ossification appears in the trochlea. This unites with the capitellum about the fifteenth year. Thus there is produced a cup of bone made up of the external condyle and that part of the bone which bears the articular surfaces. About the sixteenth or seventeenth year this unites with the shaft and ossification is complete.

Unfortunately, before this time a large proportion of the condyloid fractures occur; and it is in this connection that I desire to call attention to a condition which has been responsible for much misinterpretation in the treatment of these injuries. The men who have described new methods of treating fractures of the condyles have always evidenced extraordinary enthusiasm over their particular methods, claiming that their results were much superior to the results secured by any other method of treatment. This was because these men were investigators and had made painstaking inquiries and examinations of many cases which had been treated by the older methods and had found in many of them deformities which their own particular method obviated. Now, what is the explanation of this perennial condemnation of the old methods and approval of the new? The answer is very simple if we keep in mind these lines of ossification.

Fig. 5.—Case II. Supracondyloid Fracture, elbow flexed at an acute angle, position of fragments bad.

A child under the age of sixteen sustaining the common fracture of the external or internal condyle or the separation of the epiphysis peculiar to that age, secures a good *immediate* result, but in the healing of the fracture, which properly speaking at this age is commonly an epiphyseal separation, the intervening cartilage is converted into bone and further growth of that particular part of the articular extremity stops. The surgeon who examines the arm *immediately* after the union has taken place now declares it a good result; and it is. But if the child is ten or twelve years old ossification and longitudinal growth of bone has five years more to continue in the parts of the cartilage not involved in the injury. This growth will be unequal unless all of the osteoblastic tissue is equally converted into bone.

Thus after fracture of the external condyle the ulnar side of the lower end of the humerus continues growing after the radial side has stopped. This gives a deformity which tends to increase up to the time of ossification. Fracture of the inner condyle, carrying with it the ulnar articular surface

in the young, gradually results in obliteration of the so-called "carrying angle," and if growth continues, the next defect in the result which time produces is an actual adduction of the forearm, cubitus varus, or the "gunstock deformity" which is re-

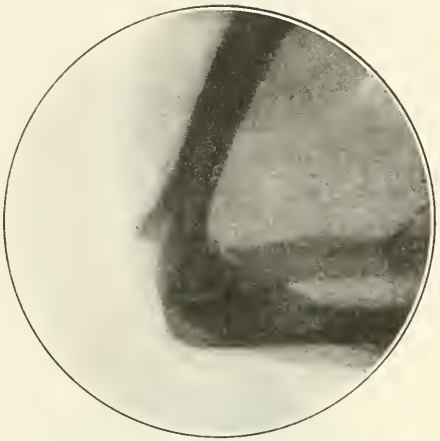

Fig. 6.—Case II. Supracondyloid Fracture; elbow flexed at a right angle, position of fragments fair.

garded as the acme of poor results. Fracture which separates the epiphysis without passing through the articular surfaces is probably a more common injury than it is supposed to be. Stimson has found a number of examples of deformity of the lower end of the humerus, due to fracture in youth, in which the bone shows no line of fracture through the articular surface of the joint. These deformities he attributes to defective healing of a separated epiphysis, and in a paper read before the New York Surgical Society in 1900,[1] he presents this thesis. These deformities are all attributed to malposition of fragments. Still, as a matter of fact, I think it is

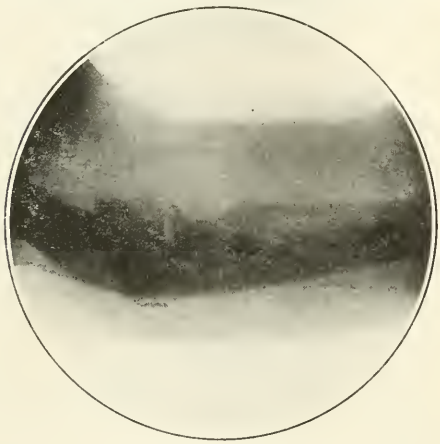

Fig. 7.—Case II. Supracondyloid Fracture; elbow straight, position of fragments good.

quite clear that they are the results of time, and there is no practical means of preventing them. The surgeon who is trying a new method does not see them; his own method has not been under observation long enough to have become subject to these deformities; he has only discovered the bad results in the older methods. But when his cases have been subjected to the mutations of time, with her immutable laws of ossification and osteogenesis, many of the elbows which he reported straight will be cited as examples of bad treatment by some of his successors.

In the most important work[2] on fractures ever published in the English language are shown pictures of humeri with a pronounced curve in the lower extremity to illustrate lateral displacement of the epiphyseal fragment. The lower extremities of these bones show no defective line of fracture union, in fact the union has been so perfect that the positive signs of fracture are not discernible, but still there is the pronounced excess of downward development of the radial side, throwing the articular surfaces inwards. These examples are so clearly the results of unequal bone growth that it is to be wondered at how they could have been attributed to defective replacement of the distal

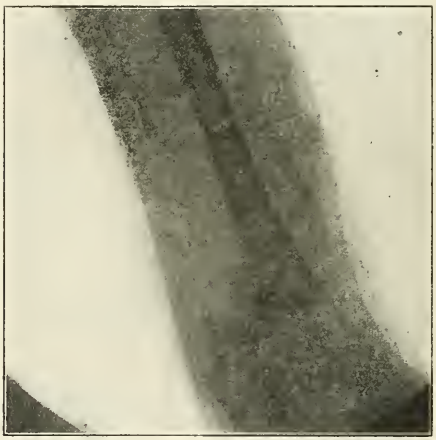

Fig. 8.—L. V. Separation of Lower Epiphysis of the Humerus; arm straight, position bad.

fragments. Such examples of deformity will occur in the practice of every surgeon unless he can bring to bear some force to modify the natural growth of bone.

Another point to which I desire to direct attention is the fear of ankylosis in these fractures of the lower end of the humerus. I feel that there is an unwarranted dread of this condition which often is responsible for damage to the arm which otherwise would not occur. I have seen arms irreparably damaged by too early attempts at passive motion, which only had the effect of disturbing the apposition. Ankylosis after fracture involving the elbow joint is almost always due to imperfect reduction. If the fragments are placed in good position in the young, we need have no fear of a stiff joint, and immobilization should be continued for at least three or four weeks or until the bone has become well united. The most important thing in the treatment of all fractures is perfect replacement and immobilization. The more perfectly these two conditions are met the less will be the callus.

[1] Stimson: *Annals of Surgery*, Vol. 32, 1900.

[2] Stimson: "Fractures and Dislocations," 1905.

Callus is largely a product of defect in these two requisites for good results. Where perfect immobilization is maintained, as in fractures of the skull or in longitudinal fractures of long bones, there is but little callus.

One of the commonest dislocations is the backward displacement of the elbow, still its differential recognition is sometimes difficult. The surgeon should not be satisfied until he has located the two epicondyles, the olecranon, and the head of the radius. With these landmarks in hand this injury is differentiated from supracondyloid fracture. The peculiar firmness or rigidity of the elbow is also quite characteristic of this dislocation. In its reduction, the method quite universally practised since the time of Sir Astley Cooper has been traction in the direction of the long axis of the humerus, with the elbow at a right angle, accompanied by traction forward in the direction of the axis of the forearm. An example of how not to reduce a backward dislocation of the elbow can be seen in the "International Text Book of Surgery," 1902, Vol. 1, p. 634. An even more objectionable method than this, commonly practised, consists in grasping the arm just above the elbow with one hand and making forward traction upon the wrist with the other hand, the dislocated elbow being fixed at a right angle. This is

Fig. 9.—L. V. Separation of Lower Epiphysis of the Humerus, moderate flexion, bad position.

the *reductio ad absurdum* as applied to dislocations of the elbow joint.

These two methods are objectionable because they depend upon stretching or tearing the two strong lateral ligaments sufficiently to allow the coronoid process to ride over the trochlea or else fracturing the process itself. They fail to take advantage of the relaxation of the ligament which is already torn in the production of the dislocation, namely, the anterior ligament of the elbow joint. The best results in reducing dislocations are secured by causing the bone to retrace the course back into the joint which it followed in becoming displaced. This dislocation occurs when the arm is nearly in the straight position, and the tearing of the anterior ligament gives the necessary relaxation to permit the coronoid process to ride over the lower end of the humerus. Thus the anterior ligament is already relaxed, and reduction is best accomplished by traction in the direction of the long axis of the arm in the straight position. If the coronoid process engages in the olecranon fossa, it is easily detached by hyperextension or by horizontal backward pressure. Rosser, as long ago as 1844, showed that hyperextension would overcome this condition, and still I have never had a house surgeon who applied it. When we examine the bones of this joint we find that the coronoid process is more than half an inch high, that means that to reduce the dislocation by the commonly applied right angle method the strong lateral ligaments must be elongated to that degree while the process plows over the trochlear surface,

Fig. 10.—L. V. Separation of Lower Epiphysis of the Humerus, extreme flexion, bad position.

or the process must be broken. The method of reduction which I have described above is, therefore, theoretically the only method, and practically I have found it most efficient.

Without entering into a general discussion of the treatment of fractures of this region, there are a few points which I should be glad to emphasize. In

Fig. 11.—L. V. Separation of Lower Epiphysis of the Humerus, one week after operation, good position. Picture taken through the plaster-of-Paris splint.

speaking of treatment, I desire to testify to the value of the treatment by the method of extreme flexion in the majority of fractures of the lower end of the humerus. The effect of flexion is beautifully shown in Figs. 1, 2, 3, and 4, Case I. This

method seems particularly applicable to fractures of the condyles. Yet there are certain cases to which it cannot be applied, and in which immobilization at a right angle or with the arm in extension gives the best position. This is shown in Case II. Figs. 5, 6, and 7. Here a supracondyloid fracture of the humerus shows bad position with the elbow in acute flexion, fair position at a right angle, and good position with the arm straight.

There are cases of condyloid fracture and epiphyseal separation with posterior displacement of the lower fragment in which manipulation and flexion fail to bring the fragment forward enough to give a good result. These are cases in which the lower fragment is prevented from moving into position by the strong unbroken ligaments. I have seen such a case of epiphyseal separation in which neither ligaments nor periosteum were broken posteriorly, the fragment being held firmly in its displaced position. In this case I exposed the fracture by a posterior incision, opened the posterior ligament and stripped up the periosteum, and replaced the fragment. It remained in good position, irrespective of flexion or extension of the forearm, and a perfect result was secured. Case III, Figs. 8, 9, 10, and 11.

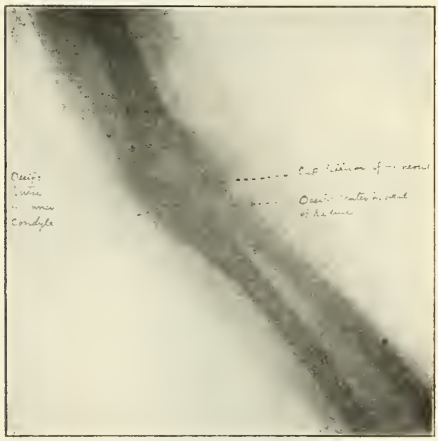

FIG. 12.—Normal elbow of a child aged 12 years.

The first essential in the treatment of elbow injuries is a familiarity with the bony landmarks; this makes accuracy of diagnosis possible. Nor should there be any hesitancy in the use of general anesthesia. For the diagnosis of fracture or dislocation one should expose both elbows and with a pencil or ink mark upon the uninjured joint the three bony points: the tips of the internal and external condyles and the tip of the olecranon. With the arm in a straight position these three points should be nearly in a straight line. With the elbow at a right angle they should make approximately an equilateral triangle. The same marks should be made on the injured side, and the examination proceeded with. Even when there is much swelling, steady pressure will reveal the condyles. The head of the radius should be identified, and with both arms extended, the carrying angle of the two sides should be compared. These are the important points of inspection. Systematic examination is important. One should take up separately each location and feature of the injury. Is the swelling or ecchymosis localized or diffuse? Locate the point of tenderness. Is crepitus present? Is either condyle movable? Examine the olecranon process. Is there fracture or dislocation of the head of the radius? Each part of the three bones entering into the joint should be considered *separately*.

No matter how skillful and thorough one is in these examinations the *x*-ray is an almost indispensable adjunct to treatment. It makes the diagnosis without inflicting pain or traumatism and without the necessity of anesthesia. Many cases which we would be satisfied with after manual examination will be found to be imperfectly replaced in the light of the *x*-ray.

The manipulation usually necessary for reduction consists in downward pressure upon the fragment, combined with traction upon the elbow and flexion to the strongest degree consistent with comfort and the integrity of the circulation. The arm is held in this position by means of a broad adhesive strap passed about the arm and forearm, with a layer of bandage interposed to keep it from the skin. To this is added a simple muslin bandage to keep the arm to the side and to support the elbow. I like to see an *x*-ray picture of the bones in this position. It sometimes reveals the fact that a trifle more flexion is desirable, or it gives one the satisfaction of knowing that the desired position has been secured. Occasionally we have a case in which extreme flexion does not bring the fragments in position. This occurs in condyloid fractures through the joint, associated with traumatic relaxation of the attached ligaments, and with a tendency of the fragment to longitudinal displacement. Some of these cases seem to do better put up at a right angle, others in the straight position in extension. I stand upon the middle ground, between the extreme flexionists of Boston and the extensionists of Philadelphia, although, as I have said, flexion is applicable to the majority of cases.

Finally there are cases in which manipulation fails to produce a satisfactory reduction. These cases should have the benefit of operative exposure of the fracture and its reduction by sight and touch. These patients have a right to expect a good joint, and the surgeon should not withhold from them any advantage which his art has to offer.

386 WASHINGTON AVENUE.

MOTOR CAR MISCARRIAGE.

BY EDWARD P. DAVIS, M.D.,

PHILADELPHIA.

AMONG the frequent causes of abortion is direct mechanical violence. This is operative in proportion to the severity of the injury inflicted and the condition of the endometrium on which the ovum is implanted. When the latter is healthy and the ovum also is not diseased, the patient will be able to withstand considerable violence without abortion.

A great shock or injury is sometimes better borne by pregnant women than frequency of repeated shock. A familiar example of this is found in abortion following the use of a sewing machine driven by the foot. On the other hand, a patient may sustain a severe fall, even fracturing a limb, and yet not abort.

The presence or absence of consciousness when

the injury is received has also a distinct bearing. Under anesthesia pregnant patients bear operations of considerable magnitude without the interruption of gestation.

The use of a motor car is so common that abundant opportunity is afforded to study its effects upon the health of patients. In the early months of pregnancy, motoring is frequently followed by abortion. The following cases are reported in illustration of this occurrence:

Case I.—Between three and four months pregnant. First pregnancy complicated at labor by premature separation of the placenta. At the second pregnancy embolism occurred threatening life. The third pregnancy terminated spontaneously without incident. The fourth pregnancy occurred when the patient was greatly fatigued, and was followed by anemia and indigestion. The patient was accustomed to a motor car, and, although employing a carriage for the greater part of the time, on one occasion went out in a motor with her husband. The car was proceeding slowly when a collision with a trolley seemed imminent; the emergency brake was used and the car stopped abruptly. The patient was not excessively frightened, as she was accustomed to motoring.

During the night following this occurrence a slight discharge of dark grumous blood occurred without pain. This continued for forty-eight hours, then increasing, becoming brighter in color and accompanied by considerable pain. The fetus was partially expelled, and the abortion terminated by the removal of the uterine contents. On examining the placenta, which was just forming, it was found that very gradual separation had occurred, and that the tissues were infiltrated and stained with blood.

Case II.—This patient had borne two children by induced labor successfully. She had never had an abortion or other complication of pregnancy. After missing one menstrual period she had symptoms indicating pregnancy, but did not believe the condition present. She was examined about six weeks after the last menstruation when the uterus was found enlarged and many of the signs of pregnancy were present. A few days afterward the patient went to New York, and shortly after traveled for the greater part of a day in her motor car. She was accustomed to motoring, having used a car constantly in going to and from her residence not far from Philadelphia.

On the morning of the day following motoring from New York, the patient thought she was taken unwell. There was very slight discharge with no pain. This condition continued for forty-eight hours until the discharge increased. A physician who saw the case considered it delayed menstruation. Four days after the trip in the motor I saw the patient and found every evidence of abortion. Under ether, dilatation and curetting were performed, when a perfect cast of the uterine cavity was removed. When this was opened it was found to contain an embryo very much younger than the period of gestation as calculated from the last menstruation. The embryo was enclosed in a thick blood clot formed by layers of fibrin of indefinite age. Hemorrhage had evidently occurred very gradually, the ovum being retained until the clot had become sufficiently large to irritate the uterus and so to cause contraction of its walls.

In both of these patients the uterus was in normal position, the pelvic viscera were normal, and the conditions favorable for the continuance of pregnancy. In case first, there was a tendency to gout and possibly arterial changes. Case second had nothing of this sort. Both patients used the best and most modern cars; one a French, the other a Packard. In both cases the cars were driven carefully by experienced persons, and motoring was done under the most favorable circumstances. It is true that in the first case a jar was given at the time when the emergency brakes were applied, but even this was not a new experience to the patient. In the second case, however, nothing whatever of this sort occurred.

The reason why motoring should be dangerous to patients in early pregnancy seems to lie in the fact that the rapid motion of a motor car subjects the patient to very frequent small jars. These are more or less violent in proportion to the character of the road and the rapidity of the car and the ease with which it works. If the patient sits upon the rear seat of a large car, the motion is usually greater and the shock received in passing over an obstacle much more than if she sits in front. In the latest cars the weight is so distributed that the back seat is more comfortable than in the older models. No matter how smoothly the motor car runs, unless it runs upon a track, its motion cannot possibly be as uniform and as smooth as that of a railway train, hence the greater danger to which it exposes the patient.

The characteristics of abortion following motoring are its slow and insidious development without bright hemorrhage and pain. The ovum evidently separates from the wall of the uterus very gradually, blood is extravasated and not poured out, and pain is not excited until the uterus is so distended by blood clot that it is made to contract. Such abortions, like most others, are, as a general rule, incomplete and require curetting to obtain a good result.

While we may recognize the motor car as a frequent cause of abortion, it is quite another matter to endeavor to lessen this accident. Pregnant patients will not stop the use of a motor car, as a rule, because pregnancy exists. Advice from a physician urging them to do so would not, in the majority of cases, be followed. Equally unsuccessful will be the attempt to secure the use of a motor car at a slower rate of speed; no self-respecting chauffeur will drive at less than fifteen miles an hour, while most prefer from twenty upward. If a machine could be so geared as not to exceed ten miles an hour, it would be, for pregnant women, a very safe but undesired vehicle. It is, however, our duty as physicians, to state to the patient that a high rate of speed, to pregnant patients, is a distinctly dangerous thing. We may also urge our patients to use the smoothest available roads, to sit upon the front seat rather than in the rear of the machine, and to avoid long journeys with the motor car. While it may be our duty to give such advice, we must not be surprised if, like much other medical advice, it is not heeded.

While motoring is dangerous in early pregnancy, in the latter months of gestation, with reasonable precautions, it may prove exceedingly useful. As a means of obtaining fresh air and inducing sleep during the heated months it is most beneficial. If patients can be induced to use reasonable precautions against shock, fatigue, and chilling the surfaces of the body, motor cars may be used under these circumstances to positive advantage.

MEDICAL PSYCHOLOGY.

By GEORGE V. N. DEARBORN, A.M., M.D., PH.D.,

BOSTON, MASS.

PROFESSOR OF PHYSIOLOGY IN TUFT'S MEDICAL AND DENTAL SCHOOLS, ETC.

If one may judge from various sorts of evidence that need not be specified here, Boston, Massachusetts, is not the only place in the world where an awakening interest in the treatment of "functional" nervous disease is obvious. It is a movement hardly less than American and European in its extent, the result of several important influences that have converged to this focus, as yet, however, none too well defined. Among these influencing tendencies of common knowledge and interest one may readily recognize, for example, those that follow. Chief of them, perhaps, are various commercial and pseudo-religious systems of mind-cure, the most widespread of which undoubtedly is Eddyism. A second influence is the failure of academic psychology to completely "make good" in the laboratories and the consequent need of its showing its practical and important applications to life,—in every phase of teaching, in therapeutics, in criminology, as well as in other aspects of human activity. Again, a general spread of knowledge as to the subconscious phases of mind and as to the nature of hypnosis and the powers of suggestion over it. The general acceptance by well-read people of the James-Lange theory of the emotions with its inevitable emphasis of the close interdependence of body and mind. The practical extinction from the beliefs and philosophic opinions of nearly all thoughtful persons of the old crass materialism. The new welcoming attitude toward the mental process assumed by the recent text-books of physiology. The lessening of church-attendance and the consequent necessary broadening of religious interest in practical human affairs. Such perhaps are the strongest of the influences that have converged of late to illuminate the importance of the mental side of man and of his diseases.

The condition of medical education in this respect is thus made somewhat anomalous, for the demand for instruction in the pathology and treatment of functional nervous affections (already met by one or two of our American medical schools) occasioned by this trend of intelligent interest, finds itself more or less handicapped at its beginning by the general lack, so conspicuous in most medical students, of scientific information as to the normal functions of the human mind. Moreover, the need of such instruction is at present not easily supplied, because the view-point of the plentiful teachers of academic psychology is so very far from that of the practical interests of medicine.

This beginning instruction in psychopathology (as for example that at Johns Hopkins and at Tufts) is, however, only one reason for the present urgent demand for normal psychology in the medical curricula. There are many older and not less pressing reasons for this inevitable requirement. These reasons are continually more insistent, and that they have not already been more widely catered to is another striking illustration of the inertia of long-established institutions. Some of these conditions have already been referred to by the present writer in an article in "Science" in 1901.

The men who control the courses of study in our medical schools are almost wholly medical graduates, and formerly even more than now the instruction was completely somatic, materialistic, so far as adequate recognition of the force of mind is concerned. The same condition obtains in some of the leading colleges still (Harvard, for example), in regard to the requirement of bodily exercise:—forty years ago the world did not realize as now the necessity of much active physical exertion to properly nourish the brain. The result is, therefore, that the present generation is to suffer needless feebleness, mental as well as bodily. So it is with the need for medical phychology.

The mental science of two or three generations back was essentially that of Aristotle and of Augustinus. It was descriptive and more or less accurate to be sure, but imbued in every part with relations "beyond" into metaphysics, epistemology, and the lofty old speculations of philosophy in general. But today has changed all that, so far as our scientific descriptive psychology is concerned. No longer do we have to think of mind as, if something more than an epiphenomenon, certainly as something less than an "internal radiance," *causa vera* of any useful process in our lives. We have extended for the purposes of science the effective range of the "sentient experience" of Hegel and of Royce and merge it in our teaching more or less completely with the energies that the first-year students of physiology measure with the work-adder and the capillary electrometer in the laboratory. In more direct terms and better, the concept of mentality that is rapidly becoming universal is that concept (formerly but a point of view) that makes a continuum of consciousness and of neurality. In the very focus of the "internal radiance," says this assumption, is attentive consciousness, then "beneath" are various but undistinguishable grades of co-consciousness, of subconsciousness, and of unconsciousness, then, at the very basis, nervous influences and energies of varying degree of force and with very various usefulness, sensory and motor. If such a notion of mind interferes with your definition of consciousness, give up the definition! on pain of being involved in that enmazing discussion going on between the "parallelists" and the "interactionists." It is by accepting this assumed but plain basis for their psychology that the teachers and practitioners of neurology and of psychiatry are left time to do their work.

Mind so understood has more practical interest for the student of the subject than any mere "epiphenomenal" consciousness could possibly have, and especially so because, thus considered, mind is useful in the conduct of life. It is in fact more than merely useful; indeed, so far as we can see, it is indispenable in any mode of efficient existence as complex as that of a mammal. Considered thus as primarily associative memory, mind offers us a satisfying explanation as to how an animal can profit by his previous experiences when traced and retained in the coordinating maze of the neural fabric.

So understood, too, mind is, so to say, of a more substantial nature than was formerly accorded it, for it finds its physical basis inherently in the neuroplasm, the protoplasm of the nerves. One could teach such a notion of the mental process to any class of medical students and be sure of being generally understood, as the writer has been, he hopes, for six or seven years past. Moreover, this is the only concept of mind that serves any purpose to the alienist, the neurologist, and the psychopathologist. Without this idea of consciousness and its subconsciousness in the working minds of the medical men and women of the future, how can one have confidence that they have a real understanding

of the majority of abnormal medical conditions?

At the present time physics and metaphysics are independently, and, for the most part, unconsciously, combining to furnish perhaps a description of the ultimate nature of mind. The most advanced physical theories are pointing out that the various "sorts" of energy are probably but aspects of one unknown mode of an experience we call motion. The "hypothetical ether" is now viewed by many physics-philosophers as of a "material" nature, and light *e.g.* has been said to be an attenuated form of "matter." One thinks of radioactivity, of electricity, of light and heat, of the forces behind osmosis and ionic action, and of all the phases of chemism as manifestations of some mode of energy that we cannot as yet denote or much less define. On the other side, the more practical and utilitarian psychologist, at least, merges mind into the associative memory of the impulses of the nervous system. And what are these impulses and this matter of protoplasm, of neuroplasm, but modes of motion? This is by no means a trend toward materialism—rather, surely, is it a tendency in the quite opposite direction, toward an understanding of all physical processes in ultimate and well-founded terms of mind. This drift of the scientific and philosophic consciousness is one of the characteristics of the times which no thoughtful person can ignore—or limit.

One, it must be admitted, cannot look forward at present hopefully to a rapidly rising standard of education preliminary to medical study. With a teaching plant unequalled and a faculty unexcelled one of the few medical schools requiring something comparable to an average bachelor's degree for admission, finds itself seeking the student-mass that would amply pay its running expenses. The medical schools, therefore, for the most part, must supply their own psychology as they do their own anatomy and much of their biology and chemistry.

There are difficulties in teaching phychology to medical students which those who have tried it readily appreciate. Primarily, for one thing, the average student of this profession is an almost discouragingly practical, not to say mercenary, young person. He is very apt to have a yearning after little that has not a dollar attached to its *terminus ad quem*, if not more immediately concerned. And as yet the relations of body and mind are not generally systematized sufficiently to make immediately obvious to the average student the actual money-value of that truer understanding of a case that knowledge of the working of the mind is sure to give. Another difficulty of successfully teaching this science to medical students is their often almost materialistic viewpoint. This forms at the outset a prejudice-barrier against all science that involves anything in any degree or sense allied to metaphysics, that opprobrious and hateful delusion of the unbalanced intellect, except to those who know something about it.

Of course, scientific, and especially medical, psychology may be as distinct from metaphysics and epistemology as is pathology proper from the current fanciful theories of immunity, or as physiology is from the theories, essentially metaphysical, by which the physics philosophers (Pierce, Ostwald, etc.,) usefully describe the possible ultimate nature of all matter. Again, we could not expect medical students to (nor do they) escape that inherent difficulty that at first meets every thinker on any topic whose subject matter is unmaterial. In physics, in discussions of energy and of the ultimate nature of matter, the same difficulty is met with, and, obviously, for precisely the same reason. It is harder at the very first to see that one can bump his personality against an alternating current of electricity from a fallen trolley-wire or against an obstinate idea in the mind of one's father quite as disastrously as against the edge of one's cellar door in the dark. For many reasons, however, this absurd primary attitude of the naïve individual does not fade from the mind of the medical student as readily as from that of the graduate student in the psychological laboratories. Finally, the oldtime confusion between academic psychology and psychical research is one of the bars to that cordial welcome which a student of practical science naturally extends toward substantial and useful knowledge. Psychology before many years undoubtedly will awaken to the long standing reproach that it is afraid to investigate these residual human phenomena, but at present certainly the science of psychology, contrary to common opinion, has less than no concern with discussions of that sort.

With all these difficulties, easily overcome by adequate instruction, the subject of medical psychology is a relatively simple science solely descriptive of easily observable facts. There need be nothing more obscure in descriptive psychology, whether medical or academic, than there is in any adequate discussion of the complexities of the marvel man. Owing to the nature of its subject-matter (immediate experience) there need not be used even the technical terms that are so great a bar at first to many of our sciences. There is little to be described outside the conscious experience, at one time or another, of the average intelligent man or woman.

The ever more insistent demands for recognition made by psychology in the medical schools might be set forth at great length, for they are cogent and many, but they here need not be so discussed. A few considerations of the sort will amply suffice to demonstrate beyond all cavil the strong need of systematic instruction in medical psychology in the middle or latter part of every medical course. For the most part the natural leaders of public opinion in this general respect, medical schools and medical education, are just at present not a little behind the common average knowledge of the wide-awake community. The somewhat hackneyed "average man" (of course, in reality there is no such) recognizes the far-pervading force of mental events and realizes the influence of that obvious progress in the spirit of mental science that is in his environment. If the particular "mental science" that influences him oftentimes is on the outer margin of charlatanry, surely it is not his fault. All the more on this account, indeed, is it the business of the medical school to show him the rightful psychology and its tremendous moment in the care of most diseases, not less than in the conduct of his daily life.

The most obvious and immediate need for systematic medical psychology comes, of course, from psychiatry and neurology. That the demand does not come even more insistently than it does from the teachers of these subjects, especially of the former, is one of the anomalies of the whole matter. When one does not expect a student to understand the deranged movements of the heart who has never seen a healthy heart or a representation of one, why should the multitude of third- and fourth-year men who know nothing of the processes of perception and imagination be expected to comprehend an hal-

lucination? or those who have never been told of the mechanism of the emotion of fear to understand the depression and misery of melancholia? One asks too much in expecting any man to really comprehend a case of paranoia who has no notion of the processes of ideation. And neurasthenia, the bread-and-butter malady to practitioners of nervous disease, does any suppose it is not so intertwined with mental relationships that to unravel it in full is to make use inevitably of no little various and intricate psychology? The modern variants of the "rest cure" require a knowledge of the motor relationships of the mind, and else this valuable system of retraining the mind back to health through controlled voluntary use of the muscles would lose much of its precision and basal usefulness.

In a less technical way, perhaps, but quite as importantly in the long run, the surgeon as a surgeon needs to be familiar with mental processes. It is especially important that he should realize the often surprising life-lengthening support and stimulation, technically called dynamogeny, that belongs to the joyful emotions. Scarcely less useful oftentimes, explain it as one may, is the vitalizing influence of determination, of vigorously expressed will to thrive and to live. Aristotle and John Hunter down to the latest of them all agree in admitting these facts, however the future science of normal medical psychology shall in detail interpret and explain them. Does the sceptic (if such, perchance persist into these "latter days") know of a single really great surgeon who does not inevitably inspire the almost perfect confidence of every patient under his care? Can the master-surgeon actually cut us up invariably so much better than his struggling neighbor in the next block uptown? Or is his greater success in part because he exacts that confidence, perhaps, but also surely, because he practises that psychology that lends to our interviews with him a confidence that stimulates every reparative influence in our organisms? These influences are real and they are vitally important. (On the other hand, fear and worry lower the visceral blood pressure.)

In a still more general way, somewhat, the successful practitioner in medical cases as distinct from surgical, consciously or otherwise, uses the principles of psychology in a very large proportion of his practice. One need not attempt the laborious task of specification here, for every practitioner must nowadays realize to some extent the mental factors in every complex disease.

The course in legal medicine in the medical schools demands for its greatest usefulness the basis of psychological knowledge which should precede it in the curriculum. The consequences of human misery and crime often depend on motives more psychical than physiologic.

In all departments of the science of medicine there is always an urgent demand for a broader outlook than the average medical student can obtain without a preliminary college course. It is easy to underestimate the influence and the importance to humanity of the profession of medicine. In the present rapid development of the means to good health and personal safety, because administered largely by unmedical officials, it is not difficult to fail to give the medical sciences their just credit for these advancements. A careful seeing, however, appreciates that medical philosophy reaches out into almost every aspect of human relationship, and that it pervades, and in considerable part directs, every phase of modern human society. That it does not do so to even a greater extent than it does is largely because the nature of personality is not adequately studied in the medical school. Many phases of the individual are often exhaustively considered, but at present it is no one's business to combine these scattered parts into the wholeness of the individual child or man or woman. And yet every patient is an individual, a personality, and has a heart and kidneys and nervous system and all the rest only as parts ministering to this personality, the only essential whole. It is one of the important tasks of the medical psychologist to weave these scattered threads of organic knowledge into this actual personality. Then at last the average physician will know, in some beginning measure at least, how to follow the sound advice of the numerous orators at commencement who advise the graduates "to treat not the disease but the individual suffering from the disease." The somatic aspects of the man are adequately treated in many, and perhaps in most essential, respects, but of the other, the inner, side of the "arc of personality" one hears but little as yet from the teaching faculties of medicine. The tide, however, is coming in!

The psychology of sex is a phase of education for which there is continually a more obvious demand from a grossly wronged and degraded society, and consequently from educators. This need has recently been more or less unconsciously, but not therefore less impressively, set forth in the treatise on Adolescence by Stanley Hall. In this particular field the departments of gynecology, of genitourinary diseases, and of psychology would meet and help each other, and with large benefit—who can doubt it?—to the future of the race.

Medical instruction in psychology undoubtedly would make the physician more sympathetic with his patients than sometimes he now is. With this added sympathy he would serve them better because more understandingly. He would tend to approach then the ideal of the oldtime family practitioner, "guide, philosopher, and friend."

Knowledge of the processes and relations of mind would be to the physician himself a source of great and unending satisfaction. Related to it is not only the knowledge of human nature, that never tiring source of interest and delight, but psychology leads outward in all directions into the true wisdom of divine philosophy.

The relations of body and mind is just now one of the most promising subjects for study, and in its medical aspects it is as important as elsewhere. This part of psychophysiology can do much for the theory and for the practice of general education, industrial education, and physical education. Nowhere, however, will its benefits to the race exceed those it can afford in medical education, for it is here that it has been thus far most completely ignored. The spirit of John Locke, Hunter, Maudsley, Huxley, Carpenter, Bell, Hack Tuke, Galton, Lewes, Hamilton, Paget, Romanes, James, Prince, and Sargent pervades to-day the whole underlying medical consciousness. This spirit materializes most usefully whenever it reaches out and strives to do its "level best" for suffering men and women, for these men and women every one are personalities with minds as well as bodies, "fire" as well as "clay." How soon will medical education openly acknowledge this and universally open its curriculum to this too long neglected phase of the vital truth?

SOME POINTS ON THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

By ALBERT H. GARVIN, M.D.,

RAY BROOK, N. Y.

ACTING SUPERINTENDENT, NEW YORK STATE HOSPITAL FOR INCIPIENT TUBERCULOSIS.

Before entering upon a discussion of the early diagnosis of tuberculosis of pulmonary type, there are a few questions that I should like to bring to your attention concerning the tuberculosis problem.

Can a person progress and advance in his lung tuberculosis and manifest no obvious symptoms of this progression?

Can a patient go into advanced tuberculosis and not know it?

What is the most important physical sign in the early diagnosis of consumption?

What is the most important working rule for the general practitioner in the fight against this disease?

To the patient early diagnosis means everything. Procrastination at the beginning greatly reduces the patient's chance for recovery. But, on the other hand, before a patient is unnecessarily damned with a diagnosis of tuberculosis it must be made on positive and certain and very definite evidence.

Given a case that presents for chest examination only for a positive or negative opinion as to the presence of tuberculosis, the problem is very much simplified so far as the physician is concerned, but this limitation of possibility of diagnosis in the cases that appear daily seldom occurs, and the family doctor must place the possibility of tuberculosis along with all the other possibilities of diagnosis that may arise in the case. The patient himself seldom presents himself for a diagnosis of tuberculosis alone.

Before considering the diagnosis it is well to define just what we mean by incipient pulmonary tuberculosis. In sanatorium work in this country tuberculosis is classified according to the scheme formulated at the first meeting of the National Association for the Study and Prevention of Tuberculosis, which met at Washington in May, 1905, and is a modified Turban's scheme.

The disease is arbitrarily divided into incipient, moderately advanced, advanced, miliary, and progressive, as follows:

Incipient.—Slight initial lesion in the form of infiltration limited to the apex or a small part of one lobe. No tuberculous complications. Slight or no constitutional symptoms (particularly including gastric or intestinal disturbances or rapid loss of weight). Slight or no elevation of temperature or acceleration of pulse at any time during the twenty-four hours, especially after rest. Expectoration usually small in amount or absent. Tubercle bacilli may be present or absent.

Moderately Advanced.—No marked impairment of function either local or constitutional. Localized consolidation moderate in extent with little or no evidence of destruction of tissue, or disseminated fibroid deposits. No serious complications.

Advanced.—Marked impairment of function, local and constitutional. Localized consolidation intense; or disseminated areas of softening; or serious complications.

Miliary and Progressive.

Many arguments of a valid nature may be made against these arbitrary definitions, for at times it seems almost impossible to classify a disease, after considering all its various phases, some of which, according to our present methods of clinical and chemical examinations, do not appear to be measurable or estimable in any sense at all.

The extent of lesion and the rapidity of onset are the two chief features that are considered, although there is no definite time limit placed upon the onset of the disease. An incipient, for instance, may remain active and continue incipient for a number of years (according to the definition), may become quiet, and may again become active in his lung inflammation. At the present time, in the main, these definitions form the most satisfactory basis for the classification of cases.

On considering this definition you will be inclined to ask, as many times I have been asked: "Well, Doctor, what does the patient complain of? What does he suffer from? What does he come to you for?" These questions are unanswerable in any positive way, and this is the whole difficulty about the diagnosis of incipient pulmonary tuberculosis. The patient complains of nothing, suffers from nothing, and in the vast majority of cases presents no obvious symptoms. The next logical question that comes from a situation like this is, "How are we to find the patient?"

When a moderately advanced or advanced case appears before you in your practice, and sits in your office chair, with his thin, cough-racked frame, and his long, bony hands on his jack-knife knees, a history seems useless and physical examination a procedure that the patient expects but which is rather philosophically performed by the doctor. What can you do for him? This thin man, with his skin deeply vein-marked and lying in folds over his bones, breathing in a labored manner, with rattles in his chest audible at six feet, listening with a leaden eye to the advice that is given him.

Every moderately advanced or advanced case that appears was at one time certainly incipient, and while his present unfortuntae condition may or may not have been avoidable, it was at least preventable. If given a favorable opportunity to recover in the beginning, in the vast majority of cases, at least 75 per cent. of those in the incipient stage would not have become advanced, soon to be numbered among the dead.

The most essential thing, after a moderately advanced or advanced case has had all the comforts provided for him and has been clearly instructed in (1) prevention, (2) daily routine of living, and (3) necessary treatment, is to consider each advanced case that appears a (4) center of infection and a point of attack in the tuberculosis problem, for so far as prevention is concerned in the advice given to this patient, prevention begins only with the diagnosis and cooperation of the patient.

An infection of immediate family or associates at work undoubtedly has occurred in the past. If possible, in the detailed history of the case itself, the source of infection should be traced. This should be possible in 50 to 75 per cent. of all histories.

In 1600 cases who officially applied through our examiners for treatment at the hospital at Ray Brook, but 325 were noted with positive history, or but one-fourth of the total number. This extremely small number has an explanation in that the patient either wilfully conceals for the sake of making his case appear more favorable in the eyes of the physician, or that he is unacquainted with his family history. That a patient will deceive his physicians as to the existence of a chronic disease in his family is a fact too well known to need much discussion.

It very frequently happens also that upon first careful history taken in a case, the patient is unable to recall the essential facts at the time the physician questions the patient, and, from no desire on the part of the patient to deceive, he simply is unable to recall the facts in his family history, and on account of memory lapse histories taken but once are frequently negative. The taking of a second history frequently obviates this source of error, and the patient, upon second repetition of the question, is able to give an extended and interested discussion upon the question that he or she was entirely ignorant of the day or the week before at previous history.

That a patient is very frequently ignorant of the exact nature of a certain chronic disease of which an immediate relative is suffering or has succumbed is often observed. This lack of information concerning the health of the family is due in part to medical deception, as the patient is often kept in ignorance of the source and exact nature of his disease, and very frequently younger members of the family are never taken into confidence at all, and do not know the essential facts.

Patients are very frequently able to describe the course and symptoms of a fatal disease in near members of the family (which has been undoubtedly tuberculosis), and by inference only can they call it this, as they have never heard definitely that their father, or mother, or sister died of this disease.

This point is very important, as frequently an incipient case of tuberculosis, who may be entirely ignorant of the fundamental symptoms of a chronic case, may not realize that his symptomless and apparent state of health is at all a forerunner of the terrible condition in which he had seen his father, or mother, or sister.

Of these 1,600 cases who were examined by our official examiners, the source of infection in 90 per cent. of the cases that gave positive family history appeared in the immediate or collateral family, and only 10 per cent. in preceding generation—illustrating the point that the recorded cases lived the greater part of their lives within the same period as the patient—10 per cent. only in the preceding generation. Also, the fact was developed that there was no predisposition traceable to father's or mother's side—each side showing approximately the same number of cases in the family.

This merely emphasizes the point that direct and long association with an infectious case is one of the chief essentials to ascribe its origin in the patient.

In 2,400 cases treated in the first two years at the Henry Phipps Institute at Philadelphia, family history was positive in 58 per cent. of all the cases, and of the cases developed in positive family history, 90 per cent. lived the greater part of their lives within the same period as the patient—either as father, mother, brother, or sister, or at place of work.

In the first 500 cases treated at Ray Brook, 41.6 per cent. gave positive family history, and also of the cases developed in history 90 per cent. of these lived within the same period as the patient.

If by far the vast majority of incipient patients show practically no symptoms, what are the signs which are most essential as beginning symptoms of pulmonary tuberculosis, and what is their significance?

Among the first 500 cases treated at the New York State Hospital, there were incipient on admission 285, or 57 per cent. of the total number; 164 were moderately advanced, or 32 per cent., and 10 per cent. were advanced. Two cases were negative and two cases gave no history.

The 285 incipient cases were tabulated, as regards first symptom, according to the best observation of the patient. All of these patients undoubtedly had tuberculosis for some time before entrance, the average period being (according to the history of the patient) about five months in those cases who had the disease less than one year, and were probably suffering from their first clinical invasion of pulmonary tuberculosis, and 31 months in duration in those who had either had tuberculosis continuously or who were undergoing treatment for their second invasion or relapse of pulmonary tuberculosis. Before treatment the patients had all been observed more or less accurately by various physicians throughout the State sending them.

Cough with expectoration as the beginning symptom was present in 23 per cent. of the cases. Cough with marked physical weakness was present in 21 per cent. as the first prominent symptom.

In regard to cough with expectoration, it is commonly thought that all tuberculous people must of necessity cough and spit, and that cough and consumption are synonymous terms. This view, which is often shared by the physicians, is misleading, and from these statistics the total number of patients who complained of cough is far less than half the total—only 44 per cent.—and these figures insist upon the point that cough, or cough with expectoration, as such are not prominent among initial symptoms of tuberculosis, although they head the list numerically.

Hemorrhage as an initial symptom was present in 19 per cent. of the 285 incipient cases. This symptom is rightly feared by both the laity and the medical men as a sure and definite symptom of tuberculosis, and if from the lungs and from no other place, such for instance as nose bleed, bleeding gum, or bleeding adenoid, practically has no other cause in the lung than tuberculosis. Excessive trauma and cardiac disease to be ruled out.

When a person has sufficient disease to cause breaking down and rupture of a blood vessel, the amount of tuberculosis is definite, and the initial hemorrhage may sometimes be quite great, but the total number of these as compared with the whole leaves hemorrhage as a diagnostic sign to be waited for as one out of the question.

On the other hand, it is perhaps rather comforting to realize that approximately 20 per cent. of the cases will in a sense diagnose themselves in the curable stage, and this relieves the physician, at least as far as the diagnosis is concerned, of one-fifth of the total problem in diagnosis, so far as these figures show.

It need not be stated that as an initial symptom hemorrhage does not play an important part in the initial symptoms as here stated, and the explanation for the large number of cases among these 285 incipients, in whom hemorrhage assisted in diagnosis, is due to selection of case, for the cases at Ray Brook are all supposed to be selected and favorable cases.

It is popularly considered that the early hemorrhage case does well, and medically this idea is more or less true. The chief explanation, it seems to me, is in an incipient case not so much that the patient has been a bleeder, as the fact that he has incipient tuberculosis and knows it and will obey

medical advice explicitly, in contradistinction to the patient who has the same extent of lesion and who has not spit blood, and who labors under the delusion that there is nothing serious the matter with him until he has become more advanced in the disease and has been convinced by a similar medical accident, or by obvious and constant symptoms.

Pneumonia as an initial symptom was present in 4 per cent. of the cases. Pleuritic pain attracted the patient's attention to some disease in the chest in 12 per cent of the cases. Grippe was noted by the patient as being the beginning of a tuberculous invasion in 4 per cent. of the cases. Chest fluid was present in 2 per cent., the diagnosis made by needle, and the patient having no idea that anything serious the matter existed until chest fluid developed apparently out of a clear sky. General weakness, loss of appetite, fever, were each described in 2 per cent. of the cases as being first possible definite symptoms in the disease.

The symptoms of onset in these incipient cases were also paralleled with those moderately advanced and advanced at the time of entrance, and they perfectly agree in percentages, the chief opinion of the patients about all the prominent symptoms of onset being that they were prominent in retrospect only as the patient had become keen from his five or six months' experience with the disease, and his education and observation in the progress of his case in those little things which indicated to him that he was or was not doing well.

When the essential facts in the family history that have bearing on the case have been considered in detail, and the conditions of work, hygiene, previous diseases, and exposure to infection that might definitely predispose the patient, have been disposed of, and the prominent symptoms of onset been developed, it would be well to consider the prominent symptoms in the early months of the disease, with their frequency of occurrence.

Obvious loss of weight is rightly accredited a prominent symptom of tuberculosis, and the lay name of the disease—consumption—derives its name from this prominent feature. It was, however, present in but 40 per cent. of the cases who were incipient on admission, and in 56 per cent. of the moderately advanced, and 60 per cent. of the advanced cases. This illustrates that the outside appearance of a patient is no real indication as to his actual physical condition, and this applies almost equally as well to the advanced as to the incipient.

Fever and chills as associated with tuberculosis are important symptoms, but were present in less than 50 per cent. of the cases in the first six months of the disease. The course of the usual septicemic relapse and the chills noted in the progress of a disease of six months duration or more has so many explanations and may be due to so many causes that nothing definite concerning them can be stated, with the exception of citation of statistics. A person may slowly and steadily advance in his chronic lung inflammation and apparently manifest no fever and no disturbance of the sympathetic nervous system.

Hemorrhage in the first six months occurred in practically twice the number of cases in which the symptom assisted in diagnosis. It was present in 40 per cent. of all the cases in the first six months of the disease.

Sputum was absent in 20 per cent., and present in slight to abundant amount in the remaining 80 per cent.

Tubercle bacilli were noted in the incipient cases as positive in 35 per cent. of the cases before entrance and in 40 per cent. after entrance. The finding of tubercle bacilli in the sputum is, of course, the one most positive proof that the patient is suffering from a tuberculous infection, but their presence is not a fundamental requisite to diagnosis, and is not to be waited for in order to definitely assign a diagnosis of tuberculosis.

When a person has arrived at the spitting stage, with bacilli, he has arrived past the stage of infiltration and must of necessity have a sizeable ulcer, with obvious destruction of tissue and degeneration, to account for the initial breakdown.

A patient who has been allowed to go on to destruction of tissue in order to develop these symptoms has a much more serious time to heal his lung inflammation than one who is treated before the initial breakdown occurs; and frequently, in addition to tuberculosis, by the time the patient has acquired his open lesion he has to fight also a mixed infection—one of the many known and obscure secondary infections, which perhaps resulted or assisted in the opening of his lesion.

In a collection of 400 cases treated at Saranac Lake and locally of incipient tuberculosis the sputum was negative in 53 per cent. of the cases, so if these cases were all tuberculous, positive sputum as a factor in diagnosis was present in only one-half of the cases.

After the symptoms in the patient have been developed physical examination follows:

As to the particular position of the patient, the standing, the sitting, and the recumbent positions all have their own advantage to develop certain signs, but the most essential thing is that the patient have the necessary clothes removed. It is simply impossible to express an opinion, either positive or negative, as to the presence or absence of signs in the chest if the physician does not listen directly to the skin. A partial exposure of the region to be examined means incomplete examination and dissatisfaction both on the part of the examiner, and sooner or later on the part of the one examined.

In regard to the anatomical limitations of the lung, I will discuss but one. The complemental pleural space is not usually carefully considered, and it extends from one-half to one and one-half inches below the free margin of the lung. The whole space that must be examined in a thorough lung examination includes the whole bony thorax from above the clavicle to the free costal margin below and the lung front and back.

In the usual procedure in complete lung examination, after mensuration and expansion have been tested bilaterally (which procedure, by the way, gives no real evidence concerning incipient pulmonary tuberculosis), it is most convenient to examine the patient either in a standing or sitting position.

I usually examine patients seated on a rotating stool, sitting beside them and not in front of them. The patient's chest on the side nearest the examiner can be auscultated and the patient can be turned facing in the opposite direction for auscultation of the opposite side. The physician is never directly in front of his patient in this way, and in case the patient accidentally coughs and has not a proper gauze handkerchief in which to cough, there is minimum danger of the patient coughing on the physician. The patient can be turned directly away from the physician for the examination of the back.

The sitting position also offers to my mind very

much, in that the physician can be more deliberate about his examination, can come back repeatedly to the same spot for auscultation, there is less mental strain entailed upon both the examiner and the one examined. Also, the strenuous deep breathing that is involved in lung examination is very fatiguing to the patient, and not infrequently causes the patient to become very dizzy, and if care is not taken it is not unusual for a patient to pass into syncope. The sitting position allows the patient to relax and to rest much more completely after periods of deep breathing than he could relax in a standing position.

Examination flat on the back in bed I have found not usually satisfactory. The patient should be either sitting over the side of the bed or sitting up; the recumbent position developing only signs which are best seen on inspection.

In regard to the formal procedure of examination, inspection is first, and in real incipient tuberculosis is negative. There may be slight retardation of movement upon the infected side. There may be slight retraction of the supraclavicular or infraclavicular space, or there might be slight atrophy of the muscles in the region of the shoulder.

The most important point in inspection is the presence or absence of Litten sign, with a note as to its extent and activity. This is the diaphragm phenomenon and is easily demonstrable in all cases that I have seen on admission. It can be developed in any position of the patient, if the patient is able and will take a full breath in and out. The chest must be properly lighted from one direction. The most easy demonstration of the sign is with the patient in a recumbent position, having him breathe deeply in and out. The active Litten may frequently be three and one-half inches in extent, and is normally two and one-half inches, and when retarded or diminished it can be easily compared with the opposite side. It may be so slight as to be but one-half inch in excursion. Its significance is that of limited movement of the inflamed part either reflexly or by adhesion, and not infrequently assists very materially in the diagnosis of a side which is at present actively tuberculous.

Slight dilatation of the pupil on the affected side sometimes occurs, and in conjunction with other unilateral signs helps a little. The explanation of this sign is due to irritation of the sympathetic nerve in the chest, probably at the root of the lung.

Palpation comes next in order, and again in the true incipient is negative. Consolidation which is dense enough to give obvious change to palpation means that the pathological process which has progressed in the lung is of much denser nature and more vast in extent than could be classified as incipient. If bronchial or rale fremitus is demonstrable, and if the case is tuberculosis, it is almost certain that it is moderately advanced or more.

Percussion, for the same reason, gives little or no evidence of help in the diagnosis of incipient tuberculosis. If the case is really incipient percussion is negative, or practically so. Still, slight changes in percussion note are obvious in cases which can be properly classified as incipient and a very slight dullness felt rather than heard, a resistance to the percussing finger assists frequently in locating the inflamed area. However, if change in the percussion note is very considerable, the pathological process which produces this change must also be quite considerable.

Auscultation is the final test, so far as physical examination is concerned, and it is the most important part in the examination. The character, the quality, the intensity, and duration of inspiration, and expiration, are the points that are noted in regard to the breath sounds, alteration in voice, both whispered and spoken, and in addition the presence or absence of any adventitious sign, either in deep breathing or developed upon cough.

The character of the breath sounds must be noted in detail. The length of the inspiratory murmur, its relative pitch, its intensity, and its quality, as compared with nearby regions and with the same area on the opposite side of the chest.

Quality is not easily definable, but change in quality is not a thing of occult nature, and while it cannot readily be defined, it is a thing easily appreciated on listening to areas in the same chest which have perhaps the same pitch and the same intensity but differ in quality.

In regard to intensity, the consolidated area of necessity does not always give increased intensity to the breath sounds. Very frequently the breath sounds may be diminished. The actual explanation for this fact is not clear, but it exists. For instance, the site of a slight pulmonary hemorrhage of an ounce or more, which does not repeat, can often not be located, and there may be no demonstrable signs within the chest at all, except at one point an area of diminished breathing. It is not infrequent to even find less than this, and often not to be able to localize at all.

The duration of inspiration and expiration are important points, especially a prolonged and intensified expiration that is localized.

After breath sounds have been thoroughly studied throughout the chest, alterations in voice and whisper follow. Unless there is some obstruction of slight nature in the bronchial tube leading to the inflamed area, which perhaps causes diminished breathing, voice and whisper are usually intensified over the infiltrated area. If an area is noted diminished in breath sounds, voice and whisper are usually correspondingly diminished. The breath, whisper, and voice are usually parallel exactly.

After the notation of the breath, whisper, and voice, the development of adventitious signs follows, and the presence of râles, their size, quality, number and time of occurrence in respiratory cycle should be noted. In many cases of incipient tuberculosis there may be no adventitious signs developed on the very deepest breathing. In fact the absence of an adventitious sign on deep breathing renders the case more favorable in prognosis when it is only on cough that signs within the chest are developed.

Auscultated cough is the one most important physical sign in the diagnosis of incipient pulmonary consumption, and it is the proper use of the cough and cough alone that enables the physician to localize disease that would repeatedly otherwise be passed over. The importance of this procedure in physical examination has not been emphasized. In a new work recently translated into the English language from the German in an immense book of 1200 pages on diagnosis, there are two lines on the significance of auscultated cough.

It is my experience that it is not so much the trouble with physicians in hearing the signs as in the difficulty of developing them. A chest which may be free on ordinary breath sounds, upon cough may develop râles of various nature. From a dry, crackling râle to a great abundance of fine showery or coarse crackling râles, which may be moist or

dry, sonorous or sibilant type, with all variations in the quality of sound to the very finest crackles. The softer and more bubbling the rale the more apt is the patient to demonstrate the rales on ordinary breathing, and the dryer and more crackling the less apt is the adventitious sound to be heard on ordinary breathing.

The patient, after expiring deeply, gives a slight hacking cough and follows this with a deep breath. The cough must not be a succession one, and must not be too loud, for frequently numerous showers of rales may be lost in the thunder of the cough of the patient, and the area of the chest noted as negative that has definite physical signs located within it. Immediately following the cough inspiration will develop the sign if present, and if rales fail to develop in this way it is not unwise to have the patient breathe out completely, then cough and breathe in.

Inspection, palpation, percussion, and auscultation of breath sounds should be done with the least possible exertion on the part of the patient, and the area in the chest, from history and physical examination thus far suspected, selected for auscultation and that part auscultated first—left apex front or behind, right apex front or behind, or both, as the case may be.

Location of lesion is approximately 60 per cent. in the right upper lobe, 25 per cent. in the left upper lobe, and 4 per cent. in the right lower, and 1 per cent. in the left lower in the 285 incipient cases that I have been citing.

After all the leading symptoms have been ascertained, the suspected area is auscultated first with cough, and if nothing is developed the remaining chest is auscultated, returning frequently to the suspected area and listening again and again to breath after cough. Frequently rales at an apex are overlooked, and it is noted that the patient has, for instance, rales from the third rib to the base, whereas, if the examiner had returned to the original site noted as negative, he would have heard rales and would have noted the presence of adventitious signs throughout the whole of one lung, instead of through the lower lobe. Frequently the rales are heard best in front or behind, usually not with the same degree of readiness at both places, unless the patient has a rather extensive infiltration.

The auscultation of the apex posteriorly may give most definite and abundant showery rales and with marked change in voice, breath, and whisper, when the anterior examination of the same apex will be almost negative, and this is as it should be, for the smaller and more localized the lesion and the fewer the sounds, the more favorable the chances for the patient. The presence of even a single rale is of suspicious import if it is constantly present.

I remember a case of incipient tuberculosis who had but one rale located at his left apex, and no other apparent demonstrable sign. His lesion was so small as to apparently give no change in voice, or in whisper, or in breath, and as to the diagnosis there can be no doubt, for this man exhibited the bacilli in his sputum for four months and recovered to an apparent state of health within a nine months' course of treatment.

After the case has been thoroughly examined the patient necessarily expects the expression of a definite opinion, especially if he has been hammered over for a half hour or more, but it does not necessarily follow that a positive or negative opinion can be definitely stated. If the physician is suspicious of the case, even though apparently negative on examination, a negative opinion may do the patient incalculable harm by giving him too great assurance that there is nothing the matter with him, and on the other hand positive opinion where there is nothing more than suspicion is not warranted by the very depressing nature of the news to the patient that he is a sufferer of the "white plague."

The best procedure, I think, in a case where uncertainty exists is to inform the patient of no definite opinion, and to state that there are no definite reasons for thinking that he is a sufferer from tuberculosis, but that the disease has not been entirely ruled out and second or third examination is of absolute necessity to express an opinion.

You all have undoubtedly had an advanced case walk into your office, so obviously diseased as to have the diagnosis written in his face, and you have passed him in to your examining room and have listened to him, and have been astonished at what you did not hear. There are days when patients even with advanced tuberculosis will have few signs, and there are parts of days when patients of incipient or moderately advanced disease may have almost absolutely no signs. A patient in the morning after his cough and expectoration have been finished has performed his pulmonary toilet, and he may be for the time being extremely free from signs, and the expression of an opinion upon the case where signs are so demonstrably variable from day to day cannot be made with any certainty upon a single examination, and if this is true of the moderately advanced and advanced case, how much more absolutely certain is it of the incipient case?

If, after repeated negative examination, if after the temperature has been carefully watched, if after the sputum with repeated examination has proven negative, and some reason, such as obvious loss of weight, or persistent rundown condition, or long exposure to infection, or unexplained rapid pulse, renders the case suspicious, the tuberculin test may render assistance.

The test is of no use in those cases which are immunized to tuberculin, as is now done in the so-called tuberculin treatment, and in those cases who have immunized themselves as it were to tuberculin, which sometimes occurs, as all cases of tuberculosis do not react to tuberculin. Fever cases render the test of no value, as the test is in itself a fever test, with certain characteristic symptoms. The test in itself is of no assistance in localizing the tuberculosis, unless there is a suspicious area.

Briefly, the test depends upon the excitation in some way of a local and general reaction as the result of irritation of the local tuberculous inflammatory area, expressing itself with the general symptoms of fever, intense pain in the back, malaise and headache, and with increase in the activity of the local signs. If the patient is afebrile, and if there is a suspected spot in the lung, all the other signs being practically negative, and the tuberculin test is given with positive fever reaction and with increase in physical signs at the area suspected, with an increase in moist signs, the test may be assumed to be positive and the case a justifiable one for treatment on the ground that the patient's malnutrition is a result of closed tuberculosis.

The administration of the test and the diagnosis varies according to the practitioner, and is usually given with the old tuberculin of Koch in doses from ½ to 10 milligrams by hypodermic until the patient

either reacts or does not react. Usually dosing the patient with half, one, two, four, eight, and ten, or one, two, four, six, and ten milligrams at intervals of from three to five days between each dose, the temperature chart being kept up continuously during that time and the patient kept in bed the full twenty-four hours after the test is given, and longer in case he reacts, the temperature being taken every two hours after the test is given, beginning about six hours after the injection. It is usually most convenient to give the injection just before the patient retires at night and to begin his fever chart at 6 in the morning, continuing throughout the day and longer if he reacts.

If the patient does not react to ten milligrams after an interval of five or six days, a second dose of ten milligrams can be repeated, and if he fails to react to this, he can be, so far as the test is concerned, considered a negative case.

The test, in my opinion, is one which should be applied very carefully, as the old tuberculin is simply a certain filtrate of cultures of the tubercle bacilli and the poison is the most powerful and potent known. It has done an excessive amount of harm in the past, and unless properly handled will do great damage, and also, if indiscriminately applied, a great number of reactions will be obtained in people in whom there is no necessity for active treatment of their latent tuberculosis. From 60 to 75 per cent. of the total population would react to tuberculin, as we are almost all of us infected with tuberculosis, but these small infections are absolutely latent and need absolutely no treatment. For instance, 60 per cent. of a certain healthy German regiment reacted to tuberculin.

The following are the points to be considered in the eye and skin tests:

Ophthalmo-Tuberculin Test of Calmette and Wolff-Eissner.—(1) Definition of test drop; (2) preparation of tuberculin solution; (3) description of reaction: (a) typical; (b) retarded; (c) prolonged.

Significance in (1) Severity: (a) redness of caruncle, (b) same plus palpebra, (c) same plus conjunctiva; (2) Cases: (a) incipient and latent; (b) moderately advanced, (c) advanced, (d) progressive, (e) nontuberculous; (3) Suspected tuberculous cases: (a) eye reacts to too strong solution, (b) susceptibility of eye to second test, (c) inert solution.

Skin Test of von Pirquet.—Applied as a pin point vaccination with old tuberculin in 10, 25, and 100 per cent. dilutions made with sterile saline solution.

In closing, there are three points that I want to again emphasize in the early diagnosis of the disease.

The first is the very great insidiousness of onset. One but needs to see a few cases of moderately advanced or advanced tuberculosis, who have in a slow and stealthy manner progressed in their lung inflammation, to realize how far a patient can go in tuberculosis and have absolutely no realization of the seriousness of his condition. It is on account of this very great insidiousness that the cases usually go into moderately advanced and advanced disease before they are discovered clinically. And it is also for this reason, more than it is the fault of the doctor or the fault of the patient, that the case thus progresses without discovery. If there were any prominent or indicative symptom, this condition would not exist, but if insidiousness is not appreciated the tuberculosis problem will not change to any very material extent, so far as the patient is concerned.

The second point is emphasis upon the most important physical procedure in the diagnosis, which is auscultated cough. A lung examination which does not necessitate the patient's coughing is not a complete examination, for a case with definite signs will be passed over and marked as negative if this is forgotten. The suspected area can be reexamined again and again during the physical examination in an attempt to develop the suspected signs.

The third, the most important working rule for the general practitioner in the fight against this disease, is family examination. In 4500 new cases of pulmonary tuberculosis that applied for treatment at the public clinics in Berlin, under the direction of Dr. Kaiserling, the families of these 4500 new cases were systematically examined for a discovery of concealed and unknown cases, and as a result of this systematic family examination in these 4500 cases, 4500 additional cases of unknown tuberculosis were discovered, many of them in an early and favorable stage for treatment, and many, of course, having gone on insidiously, were concealed bacilli bearers, unknown even to themselves.

I wish to emphasize again that the physician who sees an advanced case has not done his full duty to the patient and to the patient's family until he has definitely proved to his own satisfaction that there is along the line no concealed case that this unfortunate man has infected.

Transposition of the Viscera and Tricelian Heart.—At a recent meeting of the Royal Academy of Medicine in Ireland, A. Stokes reported the results of his dissection of a fetus which had lived for a few minutes after birth. The heart had a large single ventricle and two auricles. The left or systemic auricle had no direct communication with the common ventricle, its blood passing through a large patent foramen ovale into the right or pulmonary auricle in order to reach the ventricle. This must be an extremely rare condition. There had been a few cases recorded in which the pulmonary auricle did not communicate with the ventricle, but none, so far as Mr. Stokes could find, in which the systemic auricle did not do so. The pulmonary artery also lay behind the aorta. Professor A. H. Young lately described a case of a tricelian heart in a man aged about 37 years. In it the chambers of the heart were in their normal position, but the aorta arose in front of the pulmonary artery.—*The Lancet.*

Irregular Manifestations of Rheumatism.—In a recent discussion before the Hunterian Society on rheumatism, A. P. Luff referred to some of the irregular manifestations of the disease. He said the latter was really an affection of the white fibrous tissue, which had led Sir William Gowers to coin the word "fibrositis." The word "rheumatic" in that connection was unfortunate. The condition was frequently started by cold and wet, and it might be started by strain, as in the case of tennis elbow, golfer's elbow, etc. In the treatment, the salicylates were useless except as relievers of pain. For the fibrositis he knew nothing to equal iodide of potassium, and he gave it in the largest possible doses. The local fibrositis might be relieved by the application of heat, or by ionic medication—that is, driving in substances by the aid of electricity, after an electric light bath for fifteen minutes. In his experience there was no necessity to diet patients suffering from fibrositis; there was no reason for the belief that it was associated with gout, and he urged that the profession should finally abandon the uric acid fetish, uric acid being a harmless by-product.—*The Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 30, 1909.

THE ANTIVIVISECTION CAMPAIGN.

THE first gun of the legislative attack upon animal experimentation in this State was fired on January 21, when Senator Davis of Buffalo introduced a bill "to regulate vivisection." By its provisions animal experimentation can be practised only by those holding certificates issued by a college, hospital, or incorporated laboratory, or under the authority of the State Commissioner of Health, or of a board of health, and only in a building registered with the State Commissioner. Reports of the number of operations must be made regularly to the Commissioner. The bill also provides that the animal to be experimented upon must be under the influence of an anesthetic. Curare is specially designated as not an anesthetic in the meaning of the act. Violation of the act is made a misdemeanor, punishable by imprisonment for not less than sixty days nor more than one year, or by a fine of not less than $100 nor more than $500.

It is rather disheartening to find the same old bill with the same old sections drawn up evidently by one who knows nothing of the methods and the objects of animal experimentation, if, as was claimed, he is a friend of vivisection—dotes on it, in fact—and only seeks to regulate it so as to shield it from all further criticism; or else by one who is an enemy of scientific progress and knows that a bill with the provisions of this one would greatly hamper if it did not actually prevent all animal experimentation. Of what earthly use most of the drug experimentation would be on animals under the influence of a general anesthetic it is difficult to see, especially if the drug to be tested happened to be a local anesthetic. Moreover many of the experiments made on animals are absolutely painless and to anesthetize the animal in such a case would distress him and expose him to the danger of death; it would subject the animal to needless suffering, a thing that no scientific experimenter would ever do. When the experiment may be painful an anesthetic, either local or general, is always given, unless, as happens in a very small proportion of cases, the experiment would be vitiated were the animal insensible. "In these cases the animal must suffer, though often far less than would be supposed, for the benefit of man, as does the gelded horse or the wounded game. The use of anesthetics, therefore, cannot properly be regulated by law, for it may be necessary, though seldom, to dispense with them when the purpose of an experiment, perhaps bearing directly upon the saving of human life, would be frustrated by their use."

The phrase just quoted is from a leaflet entitled "Animal Experimentation" issued by the Committee on Experimental Medicine of the Medical Society of the State of New York. This committee has begun the publication of a series of leaflets setting forth the scientific and medical side of the antivivisection controversy. The titles of those thus far issued are: "Animal Experimentation"; "The Sense of Pain in Man and the Lower Animals," by Prof. Frederic S. Lee; "Animal Experimentation and Cancer," by Dr. James Ewing; "Animal Experimentation and Infectious Diseases," by Dr. Simon Flexner; "Animal Experimentation and the Action of Drugs," by Dr. R. A. Hatcher; "Animal Experimentation as Viewed by Laymen," quoting President Eliot of Harvard, President G. Stanley Hall of Clark University, President E. H. Capen of Tufts College, the Rt. Rev. William Lawrence, Bishop of Massachusetts, and the Rev. Dr. George Hodges, Dean of the Episcopal Theological School, Cambridge, Mass.; "Lord Cromer's Defense of Animal Experimentation"; "The Function of the Thyroid Glands—an Important Chapter of Modern Medicine Based upon Animal Experimentation," by Dr. S. J. Meltzer; "Animal Experimentation and Diphtheria," by Dr. William H. Park, and "Animal Experimentation and Tuberculosis," by Dr. Edward L. Trudeau.

Copies of these leaflets and of others to be issued can be obtained upon application to the Committee above named at the Academy of Medicine, 17 West Forty-third street. We would urge all physicians interested in medical progress to read these short articles and so provide themselves with facts in case of attack in argument by lay acquaintances. Honest but uninstructed opponents of animal experimentation would also benefit by such reading, they would be interested by the stories of scientific progress, and they would learn the other side which would be to their advantage even if it did not entirely convince them; they would at least see that vivisectors are human and humane, and that what they do is done for the advancement of medical science and for the ultimate good of the brute creation as well as of man.

THE REFEREE BOARD AND DR. WILEY.

THE report of the Referee Board appointed by President Roosevelt to review the experiments and pass upon the decisions of Dr. Wiley of the Bureau of Chemistry has recently been made public.* The Board completely reverses the conclusions of Dr. Wiley regarding the harmfulness of sodium benzoate in the quantities used by manufacturers of preserves. The inconclusiveness of his reasoning was shown in an analysis of his report published by Dr. E. E. Smith in the MEDICAL RECORD of January 2, but the Referee Board bases its conclusions on the results of experiments on "poison squads" conducted by its members. Three independent investigations were carried out: one at the medical school of Northwestern University in Chicago, under the charge of Prof. John H. Long of that in-

stitution; a second at the private laboratory of Prof. Christian A. Herter of Columbia University, New York City, and the third at the Sheffield Scientific School of Yale University in charge of Prof. Russell H. Chittenden. The results obtained in these three separate investigations were in close agreement in their essential features. The most important of the findings were:

"First—Sodium benzoate in small doses (under 0.5 gram per day), mixed with the food, is without deleterious or poisonous action, and is not injurious to health.

"Second—Sodium benzoate in large doses (up to 4 grams per day), mixed with the food, has not been found to exert any deleterious effect on the general health nor to act as a poison in the general acceptation of the term. In some directions there were slight modifications in certain physiological processes, the exact significance of which modifications is not known.

"Third—The admixture of sodium benzoate with food in small or large doses has not been found injuriously to affect or impair the quality or nutritive value of such food."

The report is signed by President Ira Remsen of Johns Hopkins University, the Chairman of the Board and by the three experimenters above mentioned. The character and scientific standing of these four members of the Board are such as to make ridiculous any charge of prejudice against Dr. Wiley or of influence by his opponents or by food manufacturers. The experiments were scientifically conducted by scientists of repute and to dispute the conclusions of these investigators would be as futile as to impugn their motives. The result bears only upon the question of experimental accuracy, and is in no sense a victory for the advocates of poor food. The friends of Dr. Wiley and all who admire the work he has accomplished in the fight for pure food will regret that his zeal carried him into error and brought upon him the humiliation of having his conclusions overthrown by more careful experimenters. But, as we have said before, this question of food preservatives is only one and perhaps the least important part of Dr. Wiley's crusade against adulteration and falsification, and we are sure he is a man of too large caliber to abandon the fight at the first defeat, especially when this defeat was due to an error of judgment and was not inflicted by the enemy.

DENTAL SURGERY.

Pari passu with the advance of civilization have the teeth of human beings degenerated. Savage and primitive races have invariably excellent teeth which last in good condition generally to extreme old age, while the finest products of the most advanced and cultured people of the world can seldom boast of a mouth full of reliable teeth after they have reached adult age. The widespread prevalence of defective teeth under modern conditions of life has been clearly shown during recent years by the large number of rejections of candidates for the British Army for this cause. The town dwellers of the present day, among the many stigmata of degeneracy which they exhibit, present more frequently than any other form that of bad teeth. In no country of the globe are defects of teeth more conspicuous than in America, and it may also be said in no country have science and art stepped in to supply and conceal the deficiencies of nature as well as in this country. American dentists are acknowledged on all hands to be at the head of their profession.

When discussing teeth it must not be forgotten that the exact cause of caries is not yet known, and that until it is accurately determined no effective steps can be taken to treat the problem in a wholly successful manner. Still much may be done even in our limited state of knowledge to improve the teeth of the rising generation. For example, it has been demonstrated with more or less certainty that children who have been fed at the breast have better developed arches than those who have been hand-fed. The action here is mechanical, yet in older children diet has much to do with the decay of teeth. Dr. L. Ottofy, in the *Dental Cosmos*, July, 1908, shows that among the Igorotes, who are inhabitants of the Philippine Islands and are classed as barbarians rather than savages, the number of those with carious teeth is only a little over 2 per cent. He states that the Filipinos have nearly 21 per cent. of carious teeth, and he attributes the difference to the character of the food used. The Igorotes practically eat no sugar, and their food requires a good deal of mastication; the Filipinos live on a soft diet containing a large amount of sugar. Dr. Ottofy attributes the prevalence of caries in the Filipinos to this extensive use of sugar in their diet, and points out that the amount of sugar imported by the various nations is in direct ratio to the amount of caries in those nations. Undoubtedly the increasing custom of giving children and even adults food requiring little mastication is prejudicial to the health of the teeth. If there is little or no use for teeth it is not unreasonable to suppose that in the course of time they will lose their strength and may eventually disappear. Again, the condition of a person's digestive organs and stomach must not be overlooked when seeking the cause of teeth decay. There are in these days an immense army of people who suffer from dyspepsia and from an abnormally acid saliva, which quickly erodes their teeth. This condition may be caused by diet or it may be a legacy from our ancestors.

Be the cause what it may, the truth stares us in the face that defective teeth are among the most prominent and unpleasant symptoms of our advanced civilization, and it behooves medical men and dentists alike to endeavor to find a remedy. It concerns physicians intimately, because a person with carious teeth is greatly handicapped from a health point of view. The introduction of medical inspection of school children, and its natural sequence of treatment, initiated in this country, and gradually being adopted in other parts of the world, should effect some improvement in the teeth of this and future generations.

ACUTE DILATATION OF THE STOMACH.

Sudden vomiting of large quantities of fluid may occur in so many functional and organic conditions that the recognition of the cause of this symptom is frequently difficult. Yet the circumstances attending it are often extremely suggestive of this or that condition that may be held responsible. A rather rare cause which, however, must be always held in mind, is the occurrence of acute dilatation of the stomach, to the consideration of which Dr. Albert G. Nicholls devotes a very interesting paper in the *International Clinics* (Vol. IV, Eighteenth Series). This accident has usually occurred in persons who have undergone an operation under general anesthesia or who have suffered from a prolonged and wasting illness; the vomitus consists of great amounts of bilious, nonfecal fluid, this point serving to distinguish the condition from an intestinal obstruction situated further down in the intestinal canal. Accompanying the vomiting there are symptoms of collapse, with subnormal temperature, sunken eyes, pinched face, and a small and rapid pulse, death finally occurring in over 65 per cent. of the cases recorded. As the condition is becoming more widely known, the mortality is diminishing, for often enough the treatment is both very simple and very effective. Numerous autopsies have shown that frequently the immediate factor that leads to the dilatation of the stomach is the occlusion of the lumen of the duodenum by the root of the mesentery and the mesenteric vessels; it is probable that the effects of anesthesia or of prolonged illness predispose the duodenal tissues to such an obstruction, and in weakening the motor activity of the stomach prevent the overcoming of any slight obstruction by the contractions of its muscular walls and the expulsion of its contents past the site of constriction. That these factors are at work is shown by the fact that thinning and degeneration of the muscularis are frequently found.

The mechanical obstruction can, however, be very effectually dealt with by proper posturing, which should consist in placing the patient on his right side or on the abdomen, while in other cases the knee chest position relieves the strain most rapidly. The stomach tube may likewise be used either preliminary to the change in the position of the patient or even before it is attempted, so that the stomach is as rapidly as possible relieved of the fluid that drags it down and aggravates the obstruction at the duodenum. Of course, a great many cases are caused by anatomical changes, such as adhesions that cannot be influenced by posturing; the latter, however, is such an easy procedure that it ought to be tried in every diagnosed or suspected case of acute gastric dilatation. If the results are not satisfactory surgical interference may be properly considered.

In addition to advising the above treatment Dr. Nicholls very properly points out that the advisability of starving and purging patients before an operation should be carefully reconsidered. This practice, together with tight bandaging and the dorsal position insisted upon for many hours or days after the operation, may have much to do with the occurrence of sudden dilatation of the stomach.

THE TRANSFER OF MORIBUND HOSPITAL PATIENTS.

A law was passed some time ago by the New York State Legislature forbidding the practice, at one time almost universal in this city, of transferring dying patients from the private hospitals to Bellevue in order to keep the mortality statistics within limits pleasing to the trustees and to the contributors of money to the institution. That the law has not entirely put a stop to the practice was made clear at an inquest recently on the body of a man who died in Bellevue. The evidence showed that the man, who had been received in one of the private hospitals, was soon thereafter transferred to Bellevue, where he died. The coroner's jury rendered a verdict in accordance with the facts and censured the hospital for having violated the law. Within a week the same hospital was again censured for another transfer of a dying patient.

A similar case occurred at another private hospital in New York last autumn. The friends of a man suffering from a cerebral hemorrhage were notified that they must remove him at once. He was moribund at the time, but his family, alarmed by the threat of the hospital superintendent, took him to a sanatorium where he died in six hours. There are institutions in this city, the superintendents of which are governed by humane motives, and where such cruelties are not tolerated, but so long as there are any officers of private hospitals, whose eyes are fixed on the annual report, and whose hearts are unmoved by the sufferings of the dying, all the hospitals in the city must lie under the suspicion of favoring such practices.

Laws are in a measure restrictive, but all laws, even that against murder, can be evaded by human cunning. The only effectual remedy against such evils lies in the creation of a sentiment reprobating them among those liable themselves to be lawbreakers. The Association of Hospital Superintendents, an excellent society which has accomplished much in the way of administrative reforms in private hospitals, can create this sentiment if it will. The majority of its members are honorable men, actuated as strongly by a desire to promote the humane side of their profession as to institute financial and administrative betterments, and we have no doubt that an official pronouncement on this subject by the Society would go far to abolish the evil.

The Effect of Menstruation Upon Gastric Secretion.

The female organism in several of its physiological functions approaches so closely to pathological conditions that the least cause, however insignificant in itself, may turn the balance on such occasions. Everyone is familiar with the picture of acute nephritis brought on during pregnancy by carelessness in diet, or the excessive nervous state that accompanies the cessation of sexual functions at the menopause in women who do not understand the necessity of plain living and avoidance of overexcitation of any character at that period. It has also been known for a long time that the mere recurrent function of menstruation is accompanied

with a great many changes in the activity of organs that would seem to be quite independent of the sexual sphere. A series of gastric analyses reported by Wolpe in the *Deutsche medizinische Wochenschrift* for December 17, 1908, shows that both the secretion and the motility of the stomach undergo a marked change in this period. Thus all examinations gave evidence of a rise in the total acidity of the gastric juice as well as in the amount of free hydrochloric acid during menstruation, even though in the premenstrual period the acidity of the juice was diminished. Coincident with this objective phenomenon the subjective complaints of the patients were increased at the time of the menstrual flow so much that they would have justified a much more serious concern for the health of the patient if the physician were not informed of the new factor introduced at those occasions. The amount and the quality of the gastric juice secreted by several of Wolpe's patients were such as to have justified the diagnosis of a transient gastrosuccorrhea. At the same time the motor function was below normal throughout the period of menstruation. Wolpe concludes that these findings should be kept in mind both in the diagnosis and in the treatment of gastic disease in women. The objective data of gastric analysis should not be obtained during the menstural period or at least not be then given the same weight as at other times; the existence of any gastric disease should lead to greater care than usual with the diet, exercise, etc., at such periods, the presence of gastric ulcer for instance calling for an especial modification of diet in order to diminish the subjective pain and the objective danger of a large hemorrhage. The general rule that applies, indeed on many occasions in the life of a woman, is to remember the closeness with which a pathological condition is approached at these times and to take the necessary precautions to ensure the maintenance of the balance in favor of health.

Mental Shock and Multiple Sclerosis.

The significance of intense psychic phenomena in the etiology of multiple sclerosis has been the subject of much discussion among neurologists and pathological anatomists. While a number of observers deny the importance of the mere psychic event in the causation of disease, and in the absence of any evidence of gross lesions postulate the existence of multiple microscopic hemorrhages and tears through the nervous substance in consequence of concussion, others cite cases in which psychic shock had occurred without any accompanying concussion and in which multiple sclerosis nevertheless followed. Wallbaum, who is inclined to share the latter view, reports in the *Deutsche medizinische Wochenschrift* for December 10, 1908, three interesting cases of this affection that had occurred in consequence of mental shock. Two of the patients were in a collision with a street car while driving a mail wagon; neither was at all hurt physically, but both suffered greatly from the mental shock of the accident. One was so unnerved that he could not continue his work, while his companion remained on duty during that day only to meet with another similar accident. Within a few months both men began to suffer from a variety of indistinct nervous symptoms which gradually developed into a complete picture of multiple sclerosis, with scanning speech, intention tremor, emotional phenomena, etc. The third patient was an engineer of a fast passenger train who on one occasion barely succeeded in preventing a collision with a freight train that was moving in the opposite direction on the same track. No physical injury whatever had occurred, yet the mental shock was intense enough to initiate nervous phenomena which likewise continued until the full development of a multiple sclerosis. Wallbaum agrees with Leyden that severe mental shock is sufficient to produce anatomical changes in the spinal cord through the vasomotor disturbances initiated by it. The cases reported by him could of course, be interpreted as merely coincidences of nervous disease following mental shock, or as due to some anatomical lesions produced by the accidents in question or by later occurrences. However, the appearance of the disease seemed to have occurred in such close relation with the psychic shock experienced by the patients that the probability of such shock serving as an etiological factor must be granted.

News of the Week.

Sanitary Science and Public Health.—Columbia University announces under this heading a course of lectures to be given at the College of Physicians and Surgeons, 437 West 59th Street, on Monday, Wednesday, and Friday afternoons during February, March, and April, at five o'clock. Admission is free and no cards are required. The program for February is as follows: February 1—The Rise and Significance of the Public Health Movement, by William Thompson Sedgwick, Ph.D., Professor of Biology, Massachusetts Institute of Technology. 3—The Great Pathological Discoveries and their Bearing upon Public Health Problems, by J. George Adami, M.D., LL.D., Strathcona Professor of Pathology, McGill University. 8—Sanitary Science: The Control of Environment, by Professor Sedgwick. 10—Modes of Transmission and Methods of Prevention of Communicable Diseases, by William Hallock Park, M. D., Director, Research Laboratories, New York City Health Department. 15—The Beginnings of Organization for Public Health Service, by John S. Billings, M.D., LL.D., Director, New York Public Library. 17—Water Supplies and Sewage Disposal, by William H. Burr, C.E., Professor of Civil Engineering, Columbia University. 24—Factors Influencing the Health and Death Rate of Cities, by Frederick Ludwig Hoffman, Statistician, Prudential Insurance Company.

Civil Service Examinations.—The United States Civil Service Commission announces an examination of February 17 and 18, to secure eligibles for the filling of seven vacancies in the position of medical inspector, at a salary of $2,000 per annum, in the Philippine service. Application should be made to the United States Civil Service Commission, Washington, D. C.

Diphtheria Closes Hospital.—Because of an epidemic of diphtheria among the nurses of the Mountainside Hospital in Monclair, N. J., the Board of Health has deemed it wise to order the hospital closed for thorough disinfection. With the exception of three who are in a serious condition, all of the patients have been transferred to their homes or are otherwise cared for, and disinfection of the hospital will be prompt and complete.

Foot and Mouth Disease.—As a result of the discovery of two new herds of animals infected with foot and mouth disease in Lancaster County, Pa.,

the quarantine on a number of counties in that State and in New York will be more rigidly enforced and indefinitely extended. The infected herds have been slaughtered; but the outbreak is considered serious because of the extraordinary measures which have been taken in the last six weeks to stamp out the disease.

Consumptives Barred.—The Louisiana State Board of Health has decided that no child suffering from tuberculosis in any form shall be allowed to attend the public schools of that State, and that no adult so affected shall be permitted to teach in the schools.

High Pneumonia Mortality.—During the week ending January 16, 150 persons in Chicago died of pneumonia, the largest number recorded for a like period for some time.

City's Clerks Consumptive.—An unusual examination took place in Brooklyn recently, when, at the request of the County Register, the 150 clerks in his office were examined by a Health Department physician. The result was six positive and eight suspected cases. The ventilation and other conditions in the office have been improved since the examination.

French Population Increases.—Statistics recently published in Paris show that the much discussed decrease in the birth rate in France has been eliminated. For the first six months of 1908, the births exceeded the deaths by 11,000; whereas in the corresponding period of the previous year, the deaths exceeded the births by 55,000.

Milk Stations.—The Association for Improving the Condition of the Poor has made an appeal for funds to carry on the work of the seven milk depots which they established in New York City last July. More than 500 babies are being cared for at the present time. During the time they have been in existence the depots have cost about $27,000, of which about $8,000 has been returned from the sale of milk to those able to pay. Trained nurses are in attendance, and a staff of twenty-nine physicians have volunteered their services.

The Chicago Medical Milk Commission was recently created by the Chicago Medical Society, and consists of Drs. I. A. Abt, M. P. Hatfield, Frank S. Churchill, J. W. Vanderslice, C. S. Bacon, and Samuel J. Walker. Its object, it is said, is to furnish "real milk," as distinguished from modified milk.

Dr. Graham Lusk was appointed Professor of Physiology in Cornell University Medical College, in New York, at a meeting of the Trustees of the university held on January 23. At present Dr. Lusk is Professor of Physiology at the University and Bellevue Hospital Medical College.

Dr. Frederick H. Dillingham was elected President of the New York Alumni of Bowdoin College at the annual dinner on January 22.

New Maternity Hospital.—The new Jewish Maternity Hospital at 207 East Broadway, New York, was opened on the afternoon of January 24. The hospital is the first of its kind to be established on the East Side, and has been established by private subscription.

Metropolitan Hospital.—Plans and specifications for improving the equipment of the Metropolitan Hospital on Blackwell's Island, New York, were approved on January 22 by the Board of Estimate. The cost is to be not more than $150,000.

Gifts to Charities.—The Rochester (N. Y.) City Hospital has received a donation of $400,000 from Mr. George Eastman, for the purpose of rebuilding the hospital and making extensive additions. Winchester, Mass., is soon to have a general hospital, for which there has been great need. As a memorial to her son, Mrs. Sophronia A. Harrington has made a gift of $50,000 to the town for this purpose.

New York Post-Graduate Medical School.—The annual dinner of the Faculty and Directors of the school was held on January 20 at Delmonico's. Mark Twain was an honorary guest and one of the speakers, among the others being Dr. Charles L. Dana and Dr. J. George Adami.

The Norwegian Hospital Alumni Association of Brooklyn celebrated its one hundredth meeting with a dinner at the home of one of the charter members, Dr. Sewell Matheson, on January 13, 1909. The Society was organized in 1898. Its first President, Dr. Robert E. Coughlin, has this year been elected again, and served as toastmaster. During the dinner the following toasts were responded to: "Humorisms," by W. Carl Schoenijahn; "The Ideal Physician," by C. Eugene Lack; "The Brooklyn Medical Man as Compared with His Brother in Manhattan," by Sewell Matheson; "Canadian Echoes," by Robert G. Moore, and "More Humor," by Louis Stork, Jr. At the close of the dinner a silent toast was given to the Norwegian Hospital, its staff, the sisters, and all who had to do with the hospital career of the individual members. The remainder of the evening was spent in listening to a literary and musical program. The officers of the Association are: *President*, Dr. Robert E. Coughlin; *Vice-President*, Dr. John H. Ohly; *Secretary and Treasurer*, Dr. Louis Stork, Jr.

Alumni Association of the Lying-In Hospital of the City of New York.—On January 12, 1909, this society was regularly organized and the following officers were elected: *President*, Dr. Asa Barnes Davis; *Vice-President*, Dr. William Preston Macleod; *Secretary*, Dr. Joseph Edward Lumbard; *Treasurer*, Dr. John Hamilton Telfair; *Editor*, Dr. C. Frederick Jellinghaus. The object of this association is to further the advancement of medicine and to promote social intercourse among its members. The Secretary's address is 1925 Seventh Avenue.

The Medical Society of the Missouri Valley.—The spring meeting of this society will be held at St. Joseph, Mo., on March 18 and 19, 1909. Dr. Herman J. Boldt of New York will deliver the address in surgery, and Dr. N. S. Davis of Chicago the medical address. The meeting will be held under the presidency of Dr. C. B. Hardin of Kansas City, and applications for a place on the program should be made to Dr. Charles Wood Fassett, Secretary, St. Joseph, Mo.

Chicago Physicians and Druggists Feast.—The Chicago Medical Society and the Chicago Retail Druggists' Association held their annual "get together" dinner recently in furtherance of a national movement to establish a code of medicopharmaceutical ethics. Dr. Alfred C. Cotton was toastmaster. Dr. Bernard Fantus spoke on "Need of a Code of Medicopharmaceutical Ethics." Other speakers were Drs. A. M. Corwin, William E. Quine, H. F. W. Spilver, C. P. Pruyn, and C. S. N. Hallberg, and T. H. Potts. One of the prominent features of the movement concerns the alleged abuses connected with the use and sale of various proprietary prepa-

rations. Another matter said to require adjustment is prescribing by druggists and the dispensing of drugs by physicians.

The Medical Society of Franklin County, Pa., held its regular annual and quarterly meeting in Chambersburg, January 19, 1909. The following officers were elected: *President,* Dr. Percy D. Hoover, Waynesboro; *Vice-Presidents,* Drs. Harry M. Miley, Chambersburg, and Ambrose W. Thrush, Chambersburg; *Secretary,* Dr. John J. Coffman, Scotland; *Assistant Secretary,* Dr. H. Clay Devilbiss, Chambersburg; *Treasurer,* Dr. Johnston McLanahan, Chambersburg; *Censor,* Dr. J. Burns Amberson, Waynesboro. Action was taken endorsing the One Board Bill just introduced into the Legislature at Harrisburg and asking the members from the county and Senatorial District to support the bill. An elaborate report was made by a committee appointed at a previous meeting, to urge the Board of Directors of the Chambersburg Hospital to make a change of ruling, which now prohibits any physician of the county from attending his own private patient, if admitted at a minimum rate, and requiring that the patient shall be attended by one or more of the staff then on duty. The report was fully endorsed and adopted with the recommendations as expressed in the report.

The Aurora (Ill.) Medical Society.—This Society met December 17 and organized a society with this name. The following officers were elected: *President,* Dr. Herman Milbacher; *Vice-President,* Robert A. Windett; *Secretary-Treasurer,* William H. Schwingel.

The Champaign (Ill.) County Medical Society, at its annual meeting, recently held, elected the following officers: *President,* Dr. William E. Schowengardt, Champaign; *Vice-President,* Dr. Fred H. Powers, Champaign; *Secretary-Treasurer,* Dr. Cyrus F. Newcomb, Champaign.

Philadelphia County Medical Society.—At the regular business meeting held January 20 the following officers were elected for the ensuing year: *President,* Dr. Frederick P. Henry; *Vice-Presidents,* Drs. William E. Parke, C. J. Hoban, F. Mortimer Cleveland, J. F. Roderer, W. H. Morrison, Frank W. Thomas, and Ernest W. Kelsey; *Secretary,* Dr. William S. Wray; *Assistant Secretary,* Dr. Alex. R. Craig; *Treasurer,* Dr. Collier L. Bower; *Censors,* Drs. J. F. Schamberg and Lewis H. Adler, Jr.; *District Censor,* Dr. M. B. Hartzell.

The Center District (N. H.) Medical Society held its eighty-seventh annual meeting at Concord on January 12. The following officers were elected: *President,* Dr. J. W. Staples, Franklin; *Vice-President,* Dr. A. K. Day, Concord; *Secretary-Treasurer,* Dr. P. T. Haskell, Concord; *Delegates to the State Convention,* Dr. E. E. Hill and Dr. S. G. Morrill, Concord.

The Hatherly (Mass.) Medical Society, at its annual meeting on January 13, elected the following officers: *President,* Dr. Gilman Osgood of Rockland; *Vice-President,* Dr. O. A. Bemis; *Secretary,* Dr. C. E. Lovell.

The York County (Me.) Medical Society held its fifteenth annual meeting on January 14, at which the following officers were elected for the ensuing year: *President,* R. S. Gove, Sanford; *First Vice-President,* C. E. Thompson, Saco; *Second Vice-President,* F. E. Small, Biddeford; *Secretary,* J. M. O'Connor, Biddeford; *Treasurer,* L. L. Powell, Saco.

The Etowah County (Ala.) Medical Society, at its annual meeting on January 7, elected the following officers: *President,* Dr. J. W. Lawrence of Turkeytown; *Vice-President,* Dr. J. H. Wood of Attalla; *Censors,* Drs. Ison and Baskin.

The Colbert County (Ala.) Medical Society, on January 7, elected the following officers for the coming year: *President,* Dr. W. H. Greer; *Vice-President,* Dr. W. J. Maxwell; *Secretary-treasurer,* Dr. E. R. Burns; *Censor,* Dr. M. Henry.

The Waterbury (Conn.) Medical Society held its annual meeting on January 11. The following officers were elected: *President,* Dr. Charles A. Monagan; *Vice-President,* Dr. John M. Benedict; *Treasurer,* Dr. Charles S. Rodman; *Secretary,* Dr. Edward F. Ashley.

The Late Dr. Quigley.—At a special meeting of the Medical Board of Fordham Hospital, January 9, 1909, the following resolutions were adopted upon the death of Dr. John J. Quigley:

WHEREAS: Through the death of Dr. John J. Quigley the Medical Board of Fordham Hospital has lost one of its original members and a former president; one who had been most actively connected with the hospital for 17 years as visiting surgeon; whose vigorous personality won for him the respect, admiration, and love of his colleagues: therefore be it

RESOLVED: That the members of the Medical Board of Fordham Hospital express their profound sorrow at the loss of their associate, and extend heartfelt sympathy to the bereaved family. And be it further

RESOLVED: That these resolutions be spread upon the minutes of the Board, that a copy be furnished to the medical press for publication, and that a further copy be transmitted to the family of the deceased.

ALEXANDER NICOLL, M.D.,
Secretary of the Medical Board.

Obituary Notes.—Dr. JOHN WALTER GRAY of Summit, N. J., died on January 22, aged 32 years. Dr. Gray was graduated from the medical department of New York University in 1897, and was a veteran of the Spanish-American war.

Dr. ALFRED J. BIGELOW of New York died at his home on January 22. He was a graduate of the medical department of the University of Buffalo in the class of 1851.

Dr. T. MORTON HILLS of Willimantic, Conn., died at his home on January 23, aged 70 years. Dr. Hills was graduated from the Yale Medical School in 1863, and immediately after graduation entered the Union Army, serving through the remainder of the Civil War as a surgeon. After leaving the army he settled in Willimantic, where he practiced for forty-two years. He was a member of the American Medical Association.

Dr. E. FRANKLIN BETTS died at Philadelphia on January 15 at the age of 64 years. He was professor of gynecology and lecturer on general medical subjects at Hahnemann Medical College, from which institution he was graduated in the class of 1869.

Dr. ANDREW HOWELL HALBERSTADT died at Pottsville, Pa., on January 19 at the age of 77 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1856. He was for many years President of the Pottsville Board of Health.

Correspondence.

THE FULGURATION TREATMENT OF CANCER.

To the Editor of the Medical Record:

Sir:—In your issue of January 23, 1909, I note an interesting comment on the possibilities of the treatment known as fulguration as applied to cancer. Besides the benefit of the vigorous reaction, the increased leucocytosis, and the mechanical action of the copious discharge resulting from the treatment, together with the escharotic action of the sparkings, de Keating-Hart avers that the high frequency spark, if properly applied, exerts a specific destructive action upon the cancerous cell. He claims that malignant cells left *in situ*, either near or at some distance from the field of operation, are, in the majority of cases, either destroyed or indefinitely retarded in their growth. In support of his theory he recites numerous cases, in some of which macroscopical and microscopical evidence of disease was untreated, and yet these malignant foci remained inactive for a period of nearly three years. If these interesting and important findings are confirmed by extensive investigation over a sufficient period of time it will indeed be a blessing to patients afflicted with this malady. That fulguration is of benefit in the treatment of cancer is shown by reports by Juge, Delherm, Czerny, Rosenkranz, Arndt, Laquer, and others, although the majority of these investigators prefer to remain noncommittal regarding the lasting qualities of the benefit obtained. I have had no experience with this method in the treatment of deep-seated cancers, tumors of the breast, etc., but I can testify to the efficiency of the treatment in the destruction of small cutaneous epitheliomata. In inoperable rodent ulcers of the face involving the deep structures, which failed to respond to the *x*-ray I have been able in some instances to check the spread of the disease and in others to obtain complete healing by this method. Small superficial tumors can be quickly and easily removed in one sitting and the scar is as good if not better than that following surgical ablation or any other method. The pain is considerable, but it lasts only for a few seconds and cocaine anesthesia may be employed if necessary. It is far too soon to advance an opinion regarding the permanence of the cure. As already stated, cases have been reported which were treated three years ago and which are well at the present time; in some of these cases diseased tissue was left in place and these foci have either disappeared or have remained inactive. It is possible that exact technique or the element of personal equation is a matter of importance in the treatment of these cases, for some of my patients after having been thoroughly treated have had a return of the disease after a few months. I admit that my technique is not exactly that advised by de Keating-Hart, the difference being that I do not employ a cool current of air or gas to overcome the heat effects of the sparks. My experience with the process of fulguration has led me to regard it as a very superior caustic or escharotic possessing many advantages over other agents employed for the same purpose, and I am not convinced as yet that it has any pronounced specific action against malignant tissue.

To de Keating-Hart must be given the credit of being the first to apply the treatment to extensive, deep-seated, and inoperable cancer and of perfecting an elaborate technique, but he was not the first man to use the high-frequency spark in the treatment of cancer. In 1900 at the International Congress of Electrology and Radiology held in Paris, and again in 1903 before the Academy of Medicine of the same city, J. A. Rivière gave an account of his experiments with the high frequency spark in the treatment of small malignant and benign cutaneous neoplasms. Dr. H. G. Piffard, in the *New York Medical Journal*, June 16, 1906, has referred to the good effects obtained in the treatment of small cutaneous cancers in this manner. Reports of the escharotic action of these sparks may also be found in the books of Allen and Freund. Rankin reported some very important observations in the treatment of benign neoplasms and hypertrophies of the skin in the *Archives of Physiological Therapy* for September, 1906. The name fulguration as suggested by Pozzi and employed by de Keating-Hart, is not a satisfactory term, for it is not suggestive of the actual procedure or of the agent employed in the treatment. It would seem that "high-frequency caustic spark," suggested by Piffard, might be a more fitting title. The advantages of this treatment are many and it undoubtedly has a brilliant future, particularly in the treatment of the various benign cutaneous neoplasms and small superficial cancers of the skin, together with many dermatological disorders, and it is also to be hoped, for the sake of humanity, that future study will support de Keating-Hart's contention regarding the specific action on the malignant cell.

Geo. M. MacKee, M.D.

616 Madison Avenue, New York.

PROPHYLACTIC CIRCUMCISION.

To the Editor of the Medical Record:

Sir:—During twenty years of active practice in general medicine and surgery it has been my experience to have seen many fads and fancies of our profession arise, flourish for a time, and then fade away. Credé's method of placental expulsion was so thoroughly ingrained in the students of my time, and later, that any expression of criticism of the practice branded one as uninformed. In the passage of years I have seen many cases of hemorrhage that in my secret mind I attributed to the too hasty removal of the secundines. At this time an expression of that opinion does not arouse professional contempt.

I have been awaiting a sensible attitude of our brethren in the matter of circumcision, but by the journals I judge that the acme of that fad has not been reached. I wish to be numbered among the pioneers who protest against the indiscriminate circumcision of male infants. In my experience it has not been usual to find in the newborn prepuces that could be retracted easily. Following the teaching I had received I had circumcised prepuces seemingly redundant and nonretractible in the newborn up to some years ago. Then, on one occasion, upon preparing to remove the foreskin, I fortunately discovered a pneumonia which delayed the operation and I did not see the child until some months after. On reexamining the patient I found the same apparent condition but upon producing stiffening I slipped the foreskin over and thereafter advised doing so daily and applying a sterile lubricant. Since that time I do not circumcise, if there is a free flow of urine, until the child is a year old, and I have found very few cases that did not yield to a gentle separation of the foreskin from the glans and after that a free slipping back of the hood. I apply cocaine to the parts, retract as far as possible, slip a probe under the sluce, or when necessary nick an opening for it to be slipped under and peel the two mucous surfaces of the glans and prepuce apart, clear the corona, clear out the smegma in the sulcus, apply a lubricant, and instruct the mother to retract daily for a spell. It is astonishing how many cases of phimosis and apparently redundant foreskin yield to this treatment. I most emphatically oppose the custom of indiscriminate circumcision and I contend that many, many cases supposedly fit for no other treatment than circumcision can be better treated by the method outlined above.

The two main arguments advanced for the routine practice of circumcision are that the prepuce causes reflex irritation and that venereal diseases are the more easily acquired where the foreskin exists. A freely gliding foreskin never irritates. Venereal infection is acquired as readily by an abraded surface uncovered as by one covered. I further contend that an exposed gland is more likely to be irritated than a covered one: furthermore the protected nerve terminals are a help to the longer preservation of potency. I could enlarge on the unsightly deformities that have come under my observation from this practice of circumcision, but I am only pleading for a common-sense stand by physicians on this fad of clipping foreskins.

J. C. Farmer,

327 Church Street, San Francisco.

OUR LONDON LETTER.

(From Our Special Correspondent.)

FERMENTED MILK DIETARY—PLAGUE, RATS, AND FLEAS—A SMALL RESEARCH HOSPITAL AT CAMBRIDGE—OBITUARY.

London, January 8, 1909.

Milk fermentation is the popular subject in London just now, and our great dairy companies are naturally exploiting it. We have consequently the option of recommending our patients several preparations, such as whole or diluted milk, curdled or soured by cultures of the different lactic acid organisms. They are also supplying tablets for making the fermented milk at home. Some practitioners have followed up the sour milk dietary with close attention since Metchnikoff's investigation of the Bulgarian yoghourt, but it must be acknowledged that a larger number look upon the

treatment as a passing craze. Elderly practitioners, or some of them, shake their heads and talk of the time when lactic acid was regarded as a malign substance, responsible for numerous forms of dyspepsia and rheumatism, and though willing to listen to an account of bacteriological investigations are doubtful as to the rehabilitation of lactic acid being permanent. They remind us of the many varieties of milk, of whey, of buttermilk, etc., which have had their day, and hope that the bacterial fermentation will prove a greater clinical advance than at first sight seems likely. Nor are such doubts surprising, and it is at least amazing to notice the irritation with which they are heard by enthusiastic bacteriologists, who account for any deviation from the expected effect by suggesting variation in the organisms present or the action of additional undetected organisms. I suppose we must admit that the bacillus of Massol found in Bulgarian sour milk and carefully investigated by Metchnikoff is better for producing the fermented milk for therapeutic purposes than most lactic acid organisms, for it grows vigorously at the body temperature and adapts itself easily to the conditions of the alimentary canal. But it also gives rise to butyric acid, to which perhaps the evils attributed formerly to lactic acid were really due. To meet this disadvantage ordinary lactic organisms can be added, since it has been shown that in their presence the production of butyric acid is restrained, provided the environment is acid, and this condition is met with in sour milk and buttermilk. The tablets on the market are apparently made with cultures of the bacilli with dried milk enough to feed them during desiccation. If kept dry and cool they can be preserved indefinitely. It is probable that some ordinary lactic organisms are present, either intentionally or by design, for if they are crushed, mixed with milk, and kept at body temperature for 10 or 12 hours a satisfactory result is obtained. One gentleman says you may just as well swallow a tablet and drink a glass of milk sweetened. I have not tried this, but it seems to suggest that for the complete rehabilitation of lactic acid as a useful agent in the economy and efficiency in some diseases we may yet come to administer it as a drug prepared by any process which gives it to us chemically pure.

The Society of Tropical Medicine has always something interesting to show or report. At its last meeting Dr. Hossack of Calcutta had a paper on plague in which he opposed the generally accepted views. Since Patton's experiments, the rat flea hypothesis has held the field, but it has been pushed, said Dr. Hossack, beyond the limits which can be justified. He admitted that to anyone opening an investigation with this view in his mind many circumstances seemed to support it, but on further investigations the facts did not accord with it. One species of rat, he declared, was as susceptible to plague as another. In the Punjab there was no *mus rattus*, and the suggestion of the commission that this variety was later than another in developing plague had no foundation in fact. The commission's endeavor to establish "a climatic plague temperature" was futile, as shown by their own experiments. Moreover, Calcutta was remarkably free from the human flea—*Pulex irritans*. Dog fleas were abundant, but rat fleas were hardly ever found there. Most of the received ideas about fleas were wrong, being based on the notion that they were evenly distributed. The contrary was the case to a remarkable extent. So, too, it was erroneous to say fleas left their hosts in the light or bit more often at night. Rat fleas had a distaste for the skin of man; only one in six attempts to make them bite the human skin succeeded. In houses in which 15 to 20 cases of plague had occurred, rat fleas were not found on careful search. He held that rat fleas will not bite a man unless they are starved, and the facts as to their distribution render their active agency in spreading plague impossible. Sir P. Manson, who occupied the chair, said that when he read the reports of the commission they convinced him, but after Dr. Hossack's paper he thought most of the members would doubt. Dr. Ford Petrie took up the defence of the commission on which he worked. He said the route of infection in rats and men was exactly the same. Of 5,000 dead rats picked up in infected houses 72 per cent. had bubœs in the neck, but no mesenteric bubœs; of rats fed on infected material only 30 had rat bubœs. Intestinal infection did not occur between rats, as they do not eat their dead fellows. The route of infection was the same in man. Attendants in plague hospitals do not take the disease; nor do guinea pigs placed in infected bedding. In the great majority of cases human infection is through the skin, not through the alimentary canal. Millions of the bacilli occupy the intestinal canal of the flea, but very few are found in the excreta of the rat. Sir Havelock Charles said the statistics on each side were so convincing that a plain man must be puzzled as to what to think. Taking everything into consideration, nobody doubted the association of rats and plague in India, and it seemed likely that fleas had something to do with the transmission. He suggested that perhaps the plague taken by the Ark of the Covenant to Ashdod and Gath might have been transmitted by fleas in the badgers' skins with which the Ark was covered. As to this amusing suggestion I should like to ask him if so, why did not the Israelites suffer after the Bethshemish outbreak? Would he hold that all the fleas escaped there and none were carried to Kiriath-jearion, where the Ark remained for twenty years? Dr. Low asked why so much was attributed to the position of the bubœs, and why in feeding experiments must they appear in the mesentery, and was not infection possible by the throat? He would like to know more of the method of making these accurate flea counts. Mr. James Canthè said experience proved that on the Gold Coast, and in Glasgow, pneumonic plague might be present and no rat infection probable. The question of transmission from man to man requires further investigation. Dr. Hossack replied to this that in Bombay only 1 per cent. were such cases, but in other districts much more, and in them no doubt direct infection was common. They counted fleas by chloroforming the animals on which they were living. The fleas were affected by the chloroform and could be easily combed out and counted.

It is very unfortunate that a small hospital devoted to research work on chronic diseases should have to be closed for want of £250 a year to keep it going. Yet this is the case with one started three years ago at Cambridge by a committee for such systematic research, pathological and clinical, and which has issued an account of its work on rheumatoid arthritis. With five beds about 100 patients have passed through the little hospital, and their cases closely investigated in all directions. Other work has also been done and of such a character that leading physicians and surgeons have issued an appeal to the profession to provide the £250 per annum to carry on the work, which sum pays all nursing and other costs. Of course those engaged in the scientific research received nothing—in fact, helped from their own purses—as so often the members of the profession do. It appears to me that the appeal of these distinguished leaders should be directed to the public—not to their poorer brethren. It is the public who will benefit. The investigators can gain no pecuniary reward. The public is not slow to subscribe when so great a guarantee of the need and value of a cause is offered.

On December 30 the last surviving daughter (Mary) of the late Dr. Bright died at the ripe old age of 93.

News has reached Jersey of the death in India of Dr. Douglas Argyll-Robertson. Dr. and Mrs. Robertson left Jersey, where he had been residing since retiring from practice, to take a trip to India and Burma.

The death is announced of Lieutenant-Colonel C. E M. Shaw, late of the Army Medical Service, who served under Lord Wolseley in the Red River expedition of 1870.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 14, 1909.

Football Injuries of the Harvard Squad for Three Years Under the Revised Rules.—The information presented by E. H. Nichols is tabulated and is to the general effect that the revised rules are accompanied by about from one-third to one-fourth as many injuries as under the old rules, the number of men in the squad being relatively the same. The author says it is curious to notice the different degrees of confusion which result from injuries. It often happens that the other players notice nothing wrong with the injured man, although from the side lines his irresponsible conduct may be evident. A man injured in the head may continue to line up for a long series of plays and may automatically go through his assignments, although if questioned he may be unable to tell his name, residence, day of the week or the name of the opposing team. Injuries specially commented on are cerebral concussion, dislocation of the knee, semilunar cartilages, synovitis, rupture of the anterior thigh muscles, dislocations of the outer end of the clavicle. Skillful players are less liable to injuries. Injured men should never resume the game until they have fully recovered. Playing to the point of exhaustion should be avoided. Proper padding also prevents many injuries.

Typhoid Carriers Found in a Series of Typhoid Fever Patients at the Time of Their Discharge from the Boston City Hospital.—The work of W. T. Graham, M. A. Bailey and C. L. and J. E. Overlander shows

that 23 per cent. of 65 cases were shown to have typhoid bacilli in their stools or urines during the ten days preceding their discharge from the hospital named. These authors say that the stools and urines of all typhoid fever patients should be examined for typhoid bacilli during the last ten days preceding their discharge from medical care and if the results are positive those patients should be detained in hospital. If at the end of ten weeks they still show bacilli, they should be allowed to leave the hospital but keep under supervision of the health authorities until they cease to be carriers. Until that is the case such typhoid distributors should have their occupations restricted. They should not be allowed to follow those pursuits which endanger others.

New York Medical Journal, January 16, 1909.

The So-called "Dangers" of Vaccination.—W. M. Welsh discusses this question and shows the falsity of the antivaccination literature. He refers to the earlier ideas regarding smallpox and vaccination. Some of the outbreaks of septic inflammation which have followed the use of a certain lot of virus have been due to defects in its preparation and in no way militate against vaccination with properly prepared virus. It is stated on good authority that such cutaneous affections as eczema, lichen, erythema, multiforme, impetigo, pemphygus, psoriasis, and a number of others, may occur as the result of vaccination. With the exception of impetigo contagiosa, it is hardly possible that any of these diseases could be inoculated with vaccine virus. But there is no doubt that the constitutional disturbances incident to vaccinia may sometimes excite into action some disease to which the subject is specially predisposed. It is impossible to communicate syphilis with bovine lymph, as the bovine animal is totally unsusceptible to this disease. The anti-vaccinationists are now directing their attention against the alleged danger of tuberculosis. Whether it is or is not possible to transmit this disease through the agency of vaccine lymph is a question that has never been fully determined. One experimenter asserts to have succeeded in developing tuberculosis in a rabbit and pig with vaccine virus taken from a tuberculous cow, while another failed to transmit the disease after injecting vaccine lymph taken from a tuberculous individual into the peritoneal cavity, under the skin, and into the anterior chamber of the eye in forty-seven animals. It is evident, therefore, that the danger is not great. But fortunately we are able to obviate entirely the slight danger that may exist. All vaccine virus is now taken from calves, and it is a well-established fact that tuberculosis in the calf is extremely rare. As a precautionary measure, in all well regulated establishments for the propagation of the bovine virus, the calves are either subjected to the tuberculin test before they are vaccinated or are autopsied before the virus is distributed for use.

The Sexual Factor in Tuberculosis.—W. H. Peters collates the views of many well-known American phthisiotherapists who all agree that the sexual appetite in the tuberculous is to be accounted for not so much by the disease itself as by the rest, forced feeding, and stimulation by large amounts of albuminous foods, alcohol, and strychnine, which figure in modern therapy. After collating these views, Peters says that he is more convinced than ever that isolation and the education received in the sanatorium are of the utmost importance before beginning the home treatment. The consumptive taking treatment at home will, as a rule, follow directions to the letter in everything except sexual matters, and many a case in both sexes would be on the road to recovery to-day, instead of gradually losing ground, if isolation was a compulsory rule instead of being insisted upon in a half-hearted way. The consensus of opinion from experienced men interviewed shows that the majority were of the opinion that increased sexual desire is not a condition due to the toxins generated in the tuberculous; that such a desire is due chiefly to idleness, and occupation on the part of the consumptive is a necessary adjunct to the treatment. Sexual indulgence, however, is a serious bar to the home treatment; married patients gain faster in sanatoria.

Journal of the American Medical Association, January 16, 1909.

Acute Glanders in Man.—F. R. Zeit says that it is comparatively easy to distinguish glanders in man from symptomatically similar conditions. The small number of cases has, he thinks, given rise to the opinion that the disease is rare in the human subject and that human susceptibility to the infection is slight; but it is probable that fatal cases occur and are reported under other diagnoses, notably smallpox. The case he reports was suspected to be smallpox, but bacteriologic examination gave a positive diagnosis of glanders. Zeit calls attention to a possible error unless one is careful in the examination of the stained smears or cultures. The deeper staining globules of the glanders bacilli may appear like groups of staphylococci, especially when the bacilli are in dense clumps, as is often the case in the thick smears from cultures. In gross appearance fresh agar cultures of the pus may also resemble those of *Staphylococcus aureus,* which may explain the frequency of such contamination reported in the literature of bacteriologic examinations of glanders. In very thin smears from glanders cultures the apparent cocci are seen to be deeply staining portions or chromatic globules within the faintly staining ground substance of the bacilli.

Cerebral Surgery.—Harvey Cushing insists on the importance of a knowledge of the nervous system and its diseases on the part of the surgeon, and the need of his taking account of the functional as well as the actual structural abnormalities he has to treat. Often the relief of the functional element is more to be desired than the cure of the organic lesion. The special points of technic on which he lays stress are, first, the anesthesia—the complete shutting off of the anesthetist from the operative field, which he accomplishes by means of an arrangement of the operative sheets that completely cuts off the anethetist, and he secures free respiration in the prone position by a special form of outrigger to the operative table. The continuous auscultation by the anesthetist of the cardiac and respiratory action is also provided for by a phonendoscope attached to the patient's chest by adhesive strips and connected with the anesthetist's ear by a device like the headgear of a telephone operator. This he considers especially important. The next thing mentioned is the subtemporal decompression trepanation as an early measure in case of possible brain tumor that cannot be exactly localized. This is performed in a safe area, and is often of itself sufficient to relieve symptoms. If localizing signs appear later, the removal operation can be performed. While in tumors above the cerebellum lumbar drainage is invaluable, Cushing calls particular attention to the dangers of lumbar puncture in cases of subtentorial tumors, from forcing down the brain substance into the spinal canal. The possibility of an unsuspected cerebellar growth, he thinks, should always be kept in mind, and the puncture not made unless the dura is exposed and ready for immediate opening in case medullary symptoms supervene. This leads him to speak of the value of a bilateral opening with wide exposure in other cases of growths difficult of access, which is also useful in preventing compression or mutilation of cerebral tissue in operation. In the older high operations for removal of the Gasserian ganglion, there was also much of compression and confusion of the temporal lobe, although no tumor was already compressing the brain, and Cushing gives special cautions for this procedure. He is able to report seventy-four operations with only two deaths, and he prefers the simple evulsion from the pons of the sensory root alone, leaving the ganglion in its bed with a half-inch gap between its hinder border and the original pontine attachment, a gap he thinks not likely to be bridged, even admitting the possibility of a central regeneration.

Mustard Packs in Bronchitis.—A. A. Herzfeld recommends mustard as a counterirritant in the treatment of capillary bronchitis and bronchopneumonia in infants and children. For the past thirteen years he has been using a method of its application which he describes as follows: Two hundred and fifty c.c. (half a pint) of water and 250 c.c. of alcohol are mixed in a large bowl; to this are added from 25 to 50 c.c., according to the severity of the case, of freshly prepared spirit of mustard. The spirit of mustard is prepared according to the German Pharmacopeia (the volatile oil is the active principle of mustard) as follows: Oil of mustard 1 part, pure alcohol 49 parts. A large piece of flannel is moistened with the mixture and wrapped around the child from the neck to the knees. The child is then enveloped in a dry sheet and the pack is left on until the skin is a bright red, usually in from 15 to 30 minutes. The child is then taken out and wrapped and left for another half hour in a pack wet with one part alcohol and two parts water. At the end of this time the child is wrapped in a dry sheet. Usually one pack causes marked improvement, but relapses are frequent and it may need renewal. Once in twenty-four hours is enough unless the indications are unavoidable. The physician should apply the first pack himself, to determine the strength needed and to instruct the parents or nurse. Herzfeld sums up the advantages of the method as follows: 1. It is surprisingly rapid in effect 2 Its light weight does not materially

embarass respiration. 3. It can be applied without removing the enfeebled patient from the bed. 4. It is inexpensive. 5. It is clean.

Cancer Cell Implantation.—E. A. Babler says that while it is clear that in many cases poor surgical technique is responsible for cancer cell liberation, it is also true that the surgeon cannot always be sure that this has not occurred. Appreciating the dangers, it occurred to him that the field of operation might be swabbed with an antiseptic solution strong enough to destroy the liberated cells without preventing primary union or causing toxic symptoms. His four years' favorable experience with the alcohol-bichloride-hydrochloric acid solution, recommended by Harrington in general surgery, led him to give it a trial in cancer operations, and for the past three months he has been applying it directly to the diseased tissues during removal, and to the wound after they had been excised, with results, he claims, that were all that could be desired. The solution destroys the superficial parts of the operative field, closes the cut ends of the capillaries and lymphatic channels, and apparently eliminates the danger of cancer cell implantation. He does not offer it as a substitute for proper surgical technique in cancer surgery, but only as a valuable and efficient aid in preventing operative infection. Experiments are now in progress with Jansen's mouse tumor to ascertain the depth reached by the destructive process after different lengths of exposure, and the results will be reported later. At present Babler applies the Harrington solution to every part of the cut surface of the cancerous part that is being removed; the growth is excised as rapidly and carefully as possible, after the infected lymphatics and their periglandular tissue have been excised. After stoppage of hemorrhage in the wound the solution is applied to the entire field for one or two minutes, according to the character of the surface. In delicate flap operations the solution is very carefully applied: it is essential that it touch all parts. Where extensive dissections have been made, it is advisable to use a rubber drain. In intra-abdominal carcinoma the solution is applied to the abdominal wound after closure of the peritoneum.

The Suture in Surgery.—H. O. Marcy says the history of the ligature and the suture is, in a measure, the exponent of the history of surgery. He reviews the use of the ligature and suture from the earliest period; the work of Celsus and Galen, of Ambrose Paré, Hunter's introduction of the ligature for aneurysm, the use of various materials for ligatures by Dr. Physick in this country, and gives considerable space to the record of Dr. Horatio Gates Jameson, whose studies, in some measure, paralleled and antedated those of Lister. The early difficulties from sepsis are noticed and the consequent neglect of the animal ligature. The monumental work of Lord Lister is, of course, duly appreciated, and the author comes to the use of buried sutures in which he claims the priority, and his search for suitable material. The defects of catgut led him to seek for a material in which the fibers ran straight, and his finding of such fibers in the tail of the opossum led him to examine other marsupials and to the discovery of the kangaroo suture. The relative merits of other materials are discussed and their disadvantages shown. Marcy criticises the use of the interrupted suture and thinks we could take a lesson from the tailor and seamstress in this particular. He commends to every aseptic surgeon familiarization with the methods of wound closure by means of various absorbable sutures, preferably tendon, and predicts not only that they will be generally adopted, but that as an important adjunct they will hold the first place in the technique of modern aseptic wound treatment.

The Lancet, January 9, 1909.

Left-sided Inguinal Hernia Containing the Vermiform Appendix.—The patient of A. D. Griffith was a woman of 31 years who five years previously, one month after confinement, noticed a swelling in the left groin which had gradually increased in size. Occasionally she felt a sharp pain on or after lying down. The swelling, which was readily reducible and seemed to consist of bowel was considered as a left inguinal hernia, about the size of a hen's egg. At the operation for radical cure the sac was found to contain the appendix, which was adherent throughout nearly its length (4 inches) to the inner wall of the hernial sac. Adhesions were broken up and traction made in the appendix to draw the cecum up to the wound. To the back of the cecum the ovary was found adherent. It was found impossible to draw the cecum sufficiently down to permit the insertion of the sutures necessary for the removal of the appendix. The peritoneum was therefore repaired over the appendix and cecum and they were returned to the abdomen. The operation for the hernia was then completed as usual. Recovery was complete. Other similar cases are collated by the author.

Two Cases of "Obscure" Rectal Pain and Their Treatment.—The cases are reported by F. C. Wallis. Case I. was that of a delicate looking man of 30 years who ten years before, after a hurried action of the bowels, had begun to have short and severe and again long continued and less severe attacks of pain, the first being occasioned by an evacuation and the second by a large variety of causes. He had operations for hemorrhoids and removal of the coccyx but without relief. The author believed that there were submucous tracts leading up the bowel from the ano-rectal junction. This supposition was verified by examination under anesthesia and the ring of mucous membrane was removed and the upper cut edge was brought down and sewed to the anal skin. Enemas were used freely, healing occurred promptly, and all the pains gradually and permanently disappeared. Case II. was that of a young man of 21 years. The conditions and treatment were the same as in Case I., and a like happy result followed operation. The author believes that these submucous tracts are the original lesions from which a large number of rectal complaints arise.

An Unusual Case of German Measles.—G. C. Garratt reports the case of a boy of 6 years who was taken with the usual symptoms of an infectious disease. The post-cervical glands were palpable, but there was no rash. A diagnosis was made of either ulcerative endocarditis or latent pneumonia. On the 6th day a typhoid rubella rash appeared, and in three days the crisis was past, all symptoms subsiding. Convalescence was uneventful. The case is of interest from the duration and severity of the prodromata, the almost entire absence of adenitis, normal fauces and but trifling catarrh. In regard to the diagnosis of this affection the author says that if the rash is seen within twelve hours and if the postannular and occipital glands are most enlarged, there is little difficulty, but if these signs are absent, if the spots on the face have coalesced or faded, or the rash on the body has become scarlet in form, diagnosis may be impossible. The author has not found the circumoral triangle of much assistance. Invasion of this area in scarlet fever, at least in adults, is by no means rare, and when the difficulty arises in a case of rubella, the rash may have left this region. Koplik's spots generally enable us to decide between rubeola and rubella.

Treatment of Old-Standing Injuries of the Wrist by Total Resection of the Carpus.—Valas says that traumatic lesions of the wrist in which efforts at reduction have failed are often capable of being greatly improved by immediate operation and sometimes even by massage alone; when, however, the lesions are of old standing, whether on account of having been overlooked or because immediate treatment has failed, they cause such inconvenience that the patient is always anxious that something should be done to help him. The majority of surgeons content themselves with removing the dislocated or fractured bones, but this method of operating generally means that successive operations have to be performed until all the carpal bones have been taken away. Valas therefore considers it better to remove the whole carpus at one sitting. In six cases which he has treated in this way he has obtained excellent results; in all these cases the carpal lesion was at least four months old and all the patients recovered complete movement of the hand. M. Valas concluded by saying that he thought that complete resection of the wrist was an excellent plan to adopt in such cases as he had described.—*The Lancet.*

Periodic Vomiting in Children.—Monlau calls our attention to a form of severe vomiting appearing suddenly in children of a neuro-arthritic type. In these families gout, rheumatism, epilepsy, tuberculosis, etc., are to be found. They are rather among those of the upper than the hospital class. Muco-membranous enteritis and appendicitis are apt to occur in the same children. Vomiting appears suddenly with little fever and great prostration. Not even ice is retained, and the slightest movement causes vomiting at first of food, later of watery fluid. The breath has the odor of acetone. Constipation is present with flaccid abdomen. Crisis occurs suddenly and the heart becomes stronger, fever passes away, appetite returns, and the child is soon well. But the attack will be repeated. The treatment of the attack consists of calomel and palliative measures. The general health must be built up by hygiene, baths, exercise, and freedom from school. Vegetables and water should be partaken of freely, and spices, acids, and sweet refrained from.—*Journal de Médecine de Paris.*

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Third Annual Meeting, Held January 25, 26, and 27, 1909

THE PRESIDENT, DR. ARTHUR G. ROOT OF ALBANY, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

Monday, January 25—First Day.

Report of the Secretary.—DR. WISNER R. TOWNSEND of New York submitted his report for the year ending December 31, 1908. The membership on December 31, 1907, was 6,323; on December 31, 1908, it was 6,595. There were dropped for non-payment of dues in 1907, 343; in 1908, 374. Membership after removal of delinquents in 1907 was 5,980; in 1908, 6,221. Percentage paid up to total membership in 1907, 94.5; in 1908, 95.0. In 1907 there were 102 deaths; in 1908, 98 deaths. In 1907 there were 57 resignations; in 1908 but 16. In 1907 there was one expulsion; in 1908, none. In 1907 there were 809 new and reinstated members; in 1908, 729. The net increase for 1908 was 241 members. Deducting the 189 reinstated members of 1907 from 343 dropped December 31, 1907, left a loss on 1907 membership of only 154, or about two and one-half per cent., a paid up percentage of 97.5 for that year, as compared with 94.5 on December 31, 1907. The increase in membership for 1908 was very small and indicated clearly, Dr. Townsend thought, that the County Societies should be more active in soliciting new members and make greater effort towards the reinstatement of the delinquents. The large majority of those dropped consisted of men who were careless in all their business relations, but a very small percentage because of inability to pay. Both of these should be encouraged to renew their membership. Both the State and County Societies needed increased revenue, and the proper and best way to secure it was by increasing the membership. There were in the State to-day nearly 4,000 physicians, non-members of this Society, who were eligible for membership in both the State and County organizations. Many of them would join if they were only asked to do so. Personal solicitation would accomplish much more than circular letters. The Treasurer's report for the year 1908 showed that the income had exceeded the expenditures by $642.46, and this result had only been accomplished by economies that in many instances were not to the advantage of the organization. It should never be the aim of the Society to accumulate a surplus, but its many activities should be encouraged and increased. This was impossible with the limited funds at the disposal of the Finance Committee, and many legitimate requests for appropriations had to be denied and others curtailed. To remedy this state of affairs all that was necessary was to increase the membership.

Report of the Committee on Publication.—DR. J. C. BIERWIRTH, Chairman, reported the resignation of Dr. J. P. Warbasse as editor of the *Journal* and the appointment of Dr. A. T. Bristow. The Committee desired to call the attention of members to the desirability of continuing the method of exclusive publication of papers read before the Society. The expense of publication had exceeded the revenue by $2,916.16, which was $166.84 more than it was in 1907. Considering the financial depression and the restrictions as to advertisements placed upon the Committee by the House of Delegates, this showing was a creditable one. The directory for 1908 was issued during the month of October, and contained 62 pages more than the previous year. The sales in New Jersey and Connecticut were small. The cost of the directory for 1908 was $7,031.86.

Report of the Committee on Public Health.—DR. JOHN L. HEFFRON, Chairman, reviewed the relations of the State and County Medical Societies to the Department of Health in the State and in the various counties in the State. The inauguration of County Bacteriological Laboratories was no longer legally impossible and many counties had taken advantage of the law and had established well-equipped laboratories. The recognition of a Department of Public Health by the national government now seemed certain. If the incoming administration failed to establish it, it would be because public sentiment was not yet sufficiently strong to force it through.

Report of the Counsel.—JAMES TAYLOR LEWIS transmitted this report. No verdict had ever been recorded against a member in any action defended by the counsel. Up to the present time the counsel had been required to defend actions for alleged malpractice in thirty-nine counties of the State. It was to be noted that there was a slight increase in malpractice actions where conspiracy, assault, or improper certification of insanity was sought to be litigated. There was evidence of increase in the abandonment of cases brought as soon as the State Society appeared by attorney for the defendant, which was perhaps the best proof of the effect which organized defence was creating in the minds of the public. The percentage of blackmailing malpractice cases had decreased and the percentage of bona fide malpractice actions had increased. Appended was a list of the new cases brought during the year 1908. He said it might be of interest, as indicating the successful progress of malpractice defense, to give the number of new cases brought for the three years last past. There were brought in 1906 thirty actions, in 1907 twenty-two, and in 1908 twenty-one, during all of which period the State Society had increased in "paid-up" membership. The amount involved in malpractice actions brought against members of the Society since the organization of the defense aggregated upward of five thousand dollars ($5,000). There were now on the counsel's books twenty three suits not finally determined.

Tuesday, January 26—Second Day.

THE PRESIDENT, DR. ARTHUR G. ROOT OF ALBANY, IN THE CHAIR.

The meeting was called to order in the Common Council Chamber, City Hall, by the president. Rev. Dr. Kittell made a prayer. After reading the minutes of the last meeting, the program of the scientific session was taken up.

President's Address.—DR. ARTHUR G. ROOT of Albany made this address, taking as the title "The Physician and Law-Making." To those who made a study of the statutes that were annually produced by the law-makers of the State of New York the most cursory examination must prove convincing that in their preparation there was a painful lack of intimate knowledge necessary to make them effective. He called attention to the efforts on the part of the medical profession to put in operation reforms redounding to the public good. The medical profession of the State of New York had steadily and consistently applied itself to the study of hygiene, and to bringing before the legislature each year enactments calculated to promote a proper understanding and application of the rules that appertained to this important subject. Proper sanitation was vastly more important to the public weal than the protection of property rights. Technical knowledge of the subject was absolutely necessary to a proper construction of a statute intended to accomplish its object and to be effective in protecting the life of an individual. The laws looking to the suppression of contagious diseases and providing for isolation, quarantine, and fumigation had robbed smallpox, scarlet

fever, and diphtheria of much of their terrors. These laws had been the direct result of study and effort on the part of the medical profession. No one but a physician of training and practice would have been competent to frame them, and no class of men other than the physician would have been so inspired "pro bono publico" as to sacrifice time and effort to the extent necessary to place them in the body of their laws and bring about their rigid enforcement. That the individual who practised the learned and responsible profession of medicine should be properly equipped, had been the aim of the society of doctors of the State of New York. With the lives of countless numbers entrusted to his care, no breadth of understanding nor extent of technical knowledge could be too great for the physician who was properly equipped to practise his profession. Recognizing this, the standard of requirements for a license to practise medicine had been steadily and consistently raised. No one could deny that the proper judges of these matters were the medical men themselves. While liberty was given to all who were duly qualified, the ridiculous claim that each school or system of medical practice should have its separate examination had been definitely and finally disallowed, and the public permanently protected. The medical profession not only preserved its own high standard, but had protected the individual from useless and dangerous experimentation. In the great and growing domain of law-making the physician was the only natural and logical authority for the subjects which affected health and life. His training and experience had educated him for this application of his talents.

The Modern Hippocrates.—Dr. A. JACOBI of New York delivered an address with this title.

The Serum Treatment of Cerebrospinal Meningitis.—Dr. L. EMMETT HOLT of New York read this paper. The serum was obtained from a horse which had been immunized by injections derived from many strains of meningococcus. In making the spinal puncture he withdrew all the fluid which would come away readily. To facilitate the injection he raised the hips and lowered the head of the patient. The technique of puncture and injections required some experience. As the dosage had not yet been measured, the serum was given in c.c. and not in units. Thirty c.c. was the initial dose. During the epidemic in New York City in 1905 the Board of Health reported 2,700 cases, with a mortality of 73.5 per cent. The serum treatment had its limitations. It had no value in cases not due to the meningococcus. Dr. Holt reported some cases that had been treated by the serum of Flexner and Jobling. The following tables were shown:

RESULTS BY AGES

Ages	Number of Cases	Recovered	Died	Mortality
0–2	59	34	25	42.4
2–5	88	63	25	28.4
5–10	104	88	16	15.4
10–20	149	108	41	27.5
20 years and over	123	75	48	39.0
Totals	523	368	155	29.6

RESULTS ACCORDING TO THE TIME OF INJECTION

Ages	First 3 Days			4–7 Days			After 7 Days		
	Number	Died	Mortality	Number	Died	Mortality	Number	Died	Mortality
0–2	11	1	9.0	11	4	21.1	29	20	71.4
2–5	22	5	22.8	40	13	32.5	26	7	27.0
5–10	49	6	12.3	37	6	16.2	18	4	22.2
10–20	54	13	24.0	54	13	24.0	41	15	36.6
20 and over	36	16	44.5	46	17	37.0	41	15	36.6
Totals	172	41	23.9	98	53	27.4	155	61	39.3

Scarlatina.—Dr. HENRY A. FAIRBAIRN of Brooklyn read this paper and made the following conclusions: (1) Difficulty was involved in definition as illustrated by the atypical forms. No symptoms were diagnostic. (2) The severity depended on the part played by the streptococcus, this germ being the basis of most of the complications. (3) The differential leucocytic count indicated pus in the absence of a rise of temperature. (4) An important factor in the treatment was attention to the skin and the toxemias. (5) The use of antitoxins heretofore had been directed against the streptococcic poison. He suggested that as the desquamation of the scales produced the disease long after the streptococci had disappeared, these should be used to obtain a vaccine or antitoxin. The streptococcus had not been found in them after a period of ninety days. (6) Quarantine should be abandoned after the first thorough desquamation. As one attack of scarlet fever generally protected the individual against others, it would seem that this serum might be used as an antiscarlatina serum. The amount of blood required for such a purpose in an individual case was small. It could frequently be obtained from a parent or relative of the patient. Its use would be attended with no risk, and possibly might be of great advantage.

Physical Training of Children.—Dr. F. W. SEARS of Binghamton read this paper. The vast majority of school children were stoop shouldered. The mental development of children was better attained by a better physical well being. He called attention to the condition of the students at West Point and Annapolis. He believed that four years of military training should be a requirement for citizenship. The fundamental part of military life was the care of the individual.

Glandular (Pfeiffer's) Fever.—Dr. W. B. GARLOCK of Little Falls said that glandular fever was a term first used by Pfeiffer in 1899. It was a sporadic or epidemic infectious disease usually occurring in children between the ages of two and ten; it might occur in adults. As a rule there was no general glandular involvement. The spleen and liver were generally tender. There was no tendency for the glands to break down. The symptoms seemed to be incident to the febrile movement. Some cases had been subjected to laboratory tests, but with negative results. Some writers claimed that the disease gained entrance through the nose and pharynx; others through the intestines. The prognosis was good, and no complications had been reported except the glandular suppuration and congestion of the retina, and these were rare. The treatment was symptomatic. He reported one case.

Dr. LEONARD W. BACON of New Haven, Conn., reported a case of glandular fever occurring in a student, which looked like a case of Hodgkin's disease. The source of the infection apparently was from the intestinal tract. It was a toxic adenitis.

Improvement in the Technique of Extraction of Cataract.—Dr. LUCIEN HOWE of Buffalo read this paper. Attention was called first to the fixation of the globe, and to a pair of forceps for accomplishing this. In the usual method of holding the conjunctiva with forceps in order to steady the globe, the conjunctiva often tore, and the globe rolled upward. This occurred even when the conjunctiva was caught with double forceps at two places. To obviate this difficulty a pair of double forceps had been so arranged as to grasp not only the conjunctiva, but also the tendon of the external and the internal rectus. The globe was thus held firmly, facilitating the puncture and counter puncture, and completion of the usual Graefe incision. The second point related to the method of extracting the lens in cases in which the lens presented properly in the wound, but could not be easily expelled. Instead of increasing the

pressure on the globe to a degree which rendered the escape of vitreous dangerous, a pair of delicate forceps had been constructed, with which to disengage the lens, and assisted in drawing it forward. Both of these forms of forceps had been used a sufficient number of times to prove their usefulness.

Dr. E. A. Davis of New York believed that any instrument which caught hold of the lens in this operation was of great aid.

Dr. Julien A. Gehrung of New York said that a vote of thanks should be tendered Dr. Howe because he simplified this operation very materially with the use of this instrument.

Meller's Operation for the Removal of the Tear Sac, with Report of Cases.—Dr. A. Edward Davis of New York read this paper. He said that a thorough knowledge of the anatomy of the lacrymal sac and the neighboring structures and a proper understanding of the relative position of the internal palpebral ligament and the anterior lacrymal crest were altogether essential in performing a successful extirpation of the tear-sac. The bloodiness of, and the great length of time required to perform the operation, together with the necessity of giving a general anesthetic had heretofore made this a formidable operation. As Dr. H. Knapp said, "extirpation of the sac is as radical an operation as an amputation, which, I repeat, should not be resorted to unless other methods of treatment have failed." Meller's operation was performed under cocaine in a relatively short time, 30 to 40 minutes, and as a rule was bloodless. The incision was made to the nasal side and above the internal canthus, and followed the anterior lacrymal crest for the distance of about two centimeters, care being taken throughout the operation not to wound the cornea and cause infection. The incision was continued through the superficial fascia, the orbicular muscle, and the deep fascia, thus exposing the sac, which was then freed by cutting the lacrymal ducts with the scissors, not tearing them away from the sac with the closed scissors, as this would likely tear away a part of the sac wall. After its removal a few drops of cocaine were instilled into the wound and the wound packed temporarily to stop all bleeding. The sac should then be stretched over a probe to make sure of its complete removal. This was important, for if any portion of the sac wall remained it should be dissected away before the wound was closed; otherwise annoying secretion continued and the success of the operation was nullified. The lacrymonasal duct should next be curetted by a small, sharp, chalazion curette, thus removing all particles of the mucous membrane which might cause the continuance of secretion. Particular care should be taken in closing the wound; that the wound edges were accurately approximated and the sutures not too tightly drawn. The operation for the removal of the tear sac was indicated first by chronic inflammation of the sac which could not be cured otherwise or had resisted treatment for a long period of time, as in such conditions as the following: (1) Large mucocele, chronic lacrymal fistula, excepting congenital capillary fistulæ. (2) Chronic stricture of the nasal duct. (3) Chronic catarrhal dacryocystitis with repeated attacks of acute phlegmonous inflammation, and ulcers of the cornea complicating this disease. (4) When an operation on the ball of the eye, as extraction of cataract, iridectomy, paracentesis, etc., was to be made on the affected side. The local anesthetic was administered by means of a hypodermic syringe with a capacity of about 1 c.c. The solution used was 1 per cent. cocaine and adrenalin chloride 1/1000, in the proportion of about 8 to 9 parts cocaine to 1 or 2 parts adrenalin. One-third of this solution was injected under the skin in the line of the intended wound; one-third of it deep in down to the periosteum immediately above the top of the lacrymal sac, just above the horizontal portion of the internal palpebral ligament; and one-third of it at the lower end of the sac deep in near the periosteum. The operation could be begun in two or three minutes after the injections were made. Five cases were reported by Dr. Davis, all of which healed by primary union, with excellent results. In no case was there much hemorrhage.

Ophthalmia Neonatorum.—Dr. Julien A. Gehrung of New York believed that the instillation of a 2 per cent. solution of silver nitrate into the eye was too irritating, and he called attention to his modification of the Credé method when the head was born. Later when the child had been cleaned and dressed, and the nurse's hands had been disinfected, the baby's eyes should again be cleansed and one drop of a 1 per cent. silver solution should be dropped into each eye, and this should be followed by a salt solution or a solution of adrenalin chloride 1-5000. This latter solution acted as an anesthetic and neutralized the action of the silver. He offered a resolution that it was the opinion of the Medical Society of the State of New York that any case of ophthalmia neonatorum proved the attendant upon that case neglectful and liable to damages for the loss of sight.

Dr. Herman J. Boldt of New York offered a resolution that there be formed a State Committee, which should communicate with each board of health and county society, and that a method should be adopted of stopping this disease, and that the State should make sufficient appropriations to the State Board of Health to carry on this work.

Dr. Gehrung withdrew his resolution.

The resolution of Dr. Boldt was referred to the House of Delegates for consideration.

Intramuscular Injections in the Treatment of Syphilis.—Dr. Victor C. Pedersen of New York read this paper. He described the injection points, six in number. By using them the same point was not used again until thirteen weeks had elapsed, the injections being given once a week. Placing the patient in such a position that would relax the glutei muscles made the injections less painful. More or less distress attended these injections. Dr. Pedersen had tried a 20 per cent. solution of salicylate of mercury, and in over three hundred injections he got good results, but the solution should be well shaken. He concluded his paper as follows: After having given or been officially responsible for something over 5,000 injections in three and a half years, he was convinced of the following facts and advantages in this method of treating syphilis: (1) The injection method of treating syphilis was the most efficient of all methods. (2) It kept the patient best under control of the physicion because he must return once or twice a week for his injections and for other treatment as needed by perhaps new symptoms. (3) Although the medicine used was an antiseptic the injection was a surgical procedure, and as such required the usual precautions of sterilization of the skin and of all instruments used. Rigid asepsis must never be neglected. (4) If the injections were slowly and gently given, with a long needle, and if the patient was in the proper position of relaxed glutei, they were in most cases virtually painless. If painful, the patient might be told that they were exactly like a bruise and of no more importance. In the bruise the extravasated blood was the foreign body, while in the injection the medicine was the foreign body, causing the slight pain by separation of the muscle fibers. (5) Node formation of longer duration than two or three days was very rare if the injection was gently and deeply made into the muscle. (6) Abscess formation might be totally avoided if sterilized fluid, needle, and skin were obtained. (7) Embolism was a real danger, but it was in fact very uncommon; in the writer's experience a little less than once in 1,000 injections. (8) Toxic accumulation was hardly excusable if palpation of

the point of the preceding injection was made at each visit, before giving the next injection. (9) The salicylate of mercury appeared to be so satisfactory that no other salt needed to be considered. The terms soluble and insoluble salts, meaning as they did laboratory solubility, were unfortunate. The soluble salts, of which the bichloride was the type, gave a very prompt and extreme reaction during the first twenty-four hours. The so-called insoluble salts, with the salicylate as a type, gave a slower, surer, and more prolonged reaction, apparently lasting five days. (10) Continuation of the injection was, so far as his experience was concerned, necessary for the usual two or three years, with one or two month's rest in each year. (11) Of course the patient's strength must be maintained at the highest possible level, and, in short, the disease must be managed like other parasitic diseases, of which tuberculosis was a type, that was, plenty of fresh air, good food, judicious exercise, and hygienic habits.

Some of the Problems Relating to Prostatectomy.—Dr. L. Bolton Bangs of New York read this paper. He believed that more careful discrimination should be exercised as to the cases operated on, and reported illustrative cases. Careful preliminary treatment should always be given. After perineal operations the fistulæ are very troublesome, and he had treated them by injections of solutions of iodine with a long and suitable sinus syringe. Dr. Bangs called attention to the possibility of the formation of postoperative stone.

Some Further Observations on Prostatectomy Based on One Hundred Cases.—Dr. J. Bently Squier of New York read this paper, calling attention to certain details in the technique in both the suprapubic and perineal operation, and reported some cases. The most frequent causes of death were uremia, sepsis, and shock.

Untoward Results from Diphtheria Antitoxin, with Special Reference to Its Relation to Asthma.—Dr. Herbert F. Gillette of Cuba said that he had published a letter about one year ago asking for reports of cases in which the injections of diphtheria antitoxin had been followed by alarming symptoms or death, especially noting whether there was any history of asthma in the cases. Out of about forty answers received the information was definite and positive concerning twenty-three cases. Sixteen of the twenty-three histories gave a history of some form of respiratory distress. Six of the sixteen cases resulted in death, and ten of the sixteen went into a state of collapse, with final recovery. Seven of the twenty-three cases gave no history of respiratory distress, and that fact was definitely determined. Four of the seven patients died and three patients went into collapse and finally recovered. The conclusions, based upon the reports received, were as follows: (1) There was a certain element of danger if horse-serum was used in subjects who suffered from any form of respiratory embarrassment, such as asthma, the so-called cardiac or renal asthma, or hay fever. (2) Collapse or death was accompanied by a respiratory crisis, and, when death occurred, it took place usually in less than ten minutes from the time of injection. (3) The administration of any form of horse-serum was liable to cause collapse or death, if the subject suffered from respiratory distress, and it was not due to any form of toxin or antitoxin, nor to any errors on the part of the maker of the serum, nor to age of the serum; but it was due to some highly organized protein which was present in the serum, and it was the reaction of the protein which caused the crisis. This reaction took place only under certain conditions. (4) The heart continued to act long after respiration had ceased. The report made by Dr. Gillette was only a preliminary one.

Epilepsy.—Dr. W. H. Kidder of Oswego said the uniform statements among all writers on symptomatology and diagnosis of epilepsy was striking. He treated of possible causes, especially the peripheral irritations which might cause an outbreak of a "latent" attack of epilepsy. Certain foods were recommended for epileptics, especially in childhood. Mistakes were made in the eating as well as the selection of food. Epileptics should never indulge in alcoholic beverages. They should be taught the art of self-control. The disease should be taken in its *ensemble* and proper lines of physical and mental hygiene with purposeful endeavors would guide the mental tendencies.

Short-duration Typhoid Fever.—Dr. Warren Coleman of New York read this paper. He said the term "short-duration" typhoid fever was used to include all types of the disease which lasted two weeks or less. This study was undertaken to discover the nature of the mild indefinite fevers, without obvious cause, lasting from about one to about two weeks, which were seen in Bellevue Hospital during every typhoid season. The recovery of the typhoid bacillus from the blood of several of them led to a review of the entire subject of the occurrence and diagnosis of the irregular forms of typhoid fever. An astonishing state of confusion existed in the literature concerning the milder and shorter forms of typhoid fever. The history of the diagnosis of the disease fell readily into two periods: (1) The period before the introduction of exact methods of diagnosis; (2) the period since the application of the Gruber reaction by Widal to the diagnosis of typhoid fever and the general employment of bacteriological methods in the diagnosis of the disease. Since there was no pathognomonic symptom of typhoid fever, the diagnosis of the disease in the first period was necessarily a matter of opinion and in disputed cases was decided by the "weight of authority." Though the occurrence of mild forms was known very early in the history of typhoid fever, and though they were frequently described, there grew up an extensive literature on mild fevers which were not generally, at least, considered to be typhoid—such, for example, as febricula, simple continued fever, mountain fever, etc. Fortunately, these terms had been for the most part discarded. In the second period the attempt had been made by a few investigators to establish, by means of exact methods of diagnosis, the identity of some of these fevers with typhoid. But when the epidemiological importance of the subject was considered, it must be admitted that the study of the milder forms of typhoid fever had been greatly neglected. No one had yet undertaken to study the bacteriology of the blood in these cases. Few of the milder forms of any disease came into Bellevue Hospital; nevertheless, in the last five years, exclusive of 1908, 10 per cent. of 229 cases of typhoid fever on the Second Medical Division had been of the short-duration variety. The proportion of mild to severe cases varied in the different years. In 1904 they constituted 25 per cent. of the typhoids. The diagnosis in twenty of the twenty-four cases was not open to doubt since it rested either upon a positive serum reaction or upon a positive blood culture. The four remaining cases were diagnosticated upon clinical evidence only, and therefore were doubtful. The symptoms of short-duration typhoid fever were not discussed as they had been so well described by Curschmann and others. Several temperature charts, however, were exhibited to illustrate in a general way the course of these forms. If one might judge from the literature, the diagnosis of mild typhoid fever was not often made. Reed, Vaughan, and Shakespeare stated after an analysis of the mortality statistics of typhoid fever in several of the larger cities of the country that "in these cities—a large percentage of the cases of this disease are not recognized as typhoid fever." Lafforgue said: "The true nature of these forms is not often recognized." Likewise, almost no attention was given in the standard American text-books to the short-duration types of typhoid fever. The diagnosis of short-duration typhoid fever could not be proven without

the assistance of laboratory methods. The fact was well known that a patient's serum might give a positive reaction to the typhoid bacillus when the patient was not suffering from typhoid fever, *e. g.*, typhoid cholecystitis and typhoid bacillus carriers. But if a positive reaction appeared transiently during the course of a febrile disease, not obviously due to some other cause, the diagnosis of typhoid fever was reasonably certain. Negative serum reactions possessed no diagnostic value unless they were obtained daily throughout the febrile period and well into convalescence. Bacteriological examinations of the blood could not be made unless one had access to a well-equipped laboratory and therefore would not be of much assistance to the general practitioner. Positive bacteriological examinations of the stools and urine did not necessarily prove that the patient had or had had typhoid fever. Finally, attention was called to the urgent need, from the epidemiological standpoint, of a more thorough study of short-duration and irregular forms of typhoid fever.

Voluntary Patients in State Hospitals for the Insane.—Dr. Albert Warren Ferris of New York read this paper. He said that this was their problem. On October 1, 1905, in the fifteen hospitals for the insane in this State, there were 26,423 patients. On October 1, 1908, there were 29,431 patients. For many years the incidence of insanity in New York State had been such that over 6,000 new cases were received annually into the State hospitals. While about 2,000 patients died annually, and many were discharged, recovered or improved, the average net increase had been 715 each year. On October 1, 1907, the net increase was 750, and on October 1, 1908, at the close of the fiscal year, they found their net increase had mounted to 1,247. To meet this condition enlargements to existing hospitals had been made year by year, as fast as money could be obtained for the purpose. The general policy had been as practised by physicians and friends of patients to encourage delay until the insanity was well established and certification, adjudication and commitment were necessary. Many justices claimed that all cases of alleged insanity should be taken into court in order that they, without knowledge of psychiatry in the vast majority of instances, might decide the matter and dismiss or commit. The damage thus done to the patient was not considered, but might never be repaired. Professor Adolf Meyer, Director of the Psychiatric Institute of the New York State Hospitals for the Insane, made the very happy suggestion that a procedure resembling quarantine should be adopted for the protection of the family and the community, and especially for the benefit of the patient. In this way "stigma" was avoided and the patient was not subjected to a court proceeding which classed him with the criminal. Thus all abuse of insane patients in jails and lockups would be avoided. To accomplish most successfully the results at which modern psychiatry aimed, cases of mental disorder should be seen early. The incipient case, the borderline case, must be reached and saved from a profound psychosis, by encouraging voluntary application for early treatment when the mental equilibrium began to waver. The State Commission in Lunacy had ordered that no patient could be admitted as voluntary "whose mind is so impaired as to render him incapable of forming a rational judgment as to the disposition of his person, or whose will is too weak as to render him incapable of resisting influence." The Commission also held that "voluntary admissions were patients whose liberty was not restricted, who were not insane within the meaning of the statute and who voluntarily remained under care and treatment." At the session of the State Legislature of 1908 the Commission introduced a bill so amending the Insanity Law as to provide for the admission into all the State hospitals except Matteawan and Dannemora of voluntary patients upon their written application, pursuant to regulations of the Commission. The Commission had ruled that no alcoholic patients without definite psychoses and no cases of drug habit without psychoses should be thus admitted. Admission of voluntary patients had proved a success in Pennsylvania, Illinois, and especially Massachusetts. In McLean Hospital, Waverly, Mass., about 35 per cent. of the patients were admitted as voluntary. Its percentage of recoveries averaged nearly 29. Their duty was to ascertain the causes of the alarming overproduction of insanity; to teach the people what were the dangers to avoid; to restrict, by law, demoralizing influences; and while there was still easy access to the patient's confidence and to his real thoughts, to adjust him to his environment, explain and harmonize his troubles and relieve his physical disorders. To accomplish these things successfully and to any extent, the patient must be seen very early. Hence, the voluntary admissions.

Dr. R. H. Hutchings of Ogdensburg said that he thought it might be interesting to the members of the society to learn of the experience at Ogdensburg with voluntary commitments. This law had been in operation since last June. Only nine patients had been admitted under the act. All came realizing that something was wrong with their minds. He related the histories of three cases; the patients were not insane, but were drifting that way.

Dr. William S. Ely of Rochester emphasized the importance of having psychiatric wards in every general hospital.

Dr. Edward D. Fisher of New York favored the early treatment of such cases and believed Dr. Ely's suggestion was good.

Dr. W. H. Kidder of Oswego said that civilization was so complicated that a greater and greater number of people could not adjust themselves to their environment.

Dr. Ferris said that the State Commission in Lunacy agreed with Dr. Ely and Dr. Fisher, and would like to have psycopathic wards in every general hospital, but required that those patients who voluntarily committed themselves should have the same care as the advanced cases. There should be a resident physician for their care. He asked that the patients should be sent in earlier; by so doing they could be sent out earlier. This would be a saving of money for the State. He asked that the appropriations for State hospitals be not cut down, but that patients be sent in earlier. The cost per annum of each patient in the State hospitals was very low, $179.60.

The First Interview with the Patient.—Dr. William S. Ely of Rochester said that the first examination of a patient was often inadequate and led to erroneous diagnoses. In his paper he considered four phases of the subject: (1) Search for causes of numerous disturbances that often received only symptomatic treatment; (2) the correct estimate of nutritive changes. He believed that scales were as important as a microscope in the physician's office. (3) He called attention to the significance of heredity, and said that both moral and physical disturbances were often due to hereditary influences. Every one had hereditary limitations which largely explained problems of insanity, criminality, degeneracy, and accounted for differences between individuals in health and when diseased. (4) The psychical aspects of many disorders were largely neglected. This neglect accounted for the existence of Christian Science and like cults, and reflected unfairly upon the medical profession.

X-Ray Treatment of Leukemia.—Dr. W. J. Schuyler of Utica reported a case of successful treatment of leukemia by means of the *x*-ray.

Brief Review of the Application of Roentgen Rays in Diagnosis.—Dr. E. W. Caldwell of New York spoke of the limitations of early work in *x*-ray diagnosis. Its development should include new applications. Dr Caldwell presented some lantern slides showing (1) the localization of foreign bodies, (2) fractures and dislocations;

(3) bone diseases; (4) urinary calculi; (5) pulmonary tuberculosis; (6) tumors of the mediastinum; (7) empyema of the accessory sinuses, and (8) dental applications.

Officers.—The result of the election of officers was then announced as follows: *President,* Dr. Charles P. Stockton of Buffalo; *First Vice-President,* Dr. D. C. Moriarta of Saratoga Springs; *Second Vice-President,* Dr. J. H. Glass of Utica; *Third Vice-President,* Dr. J. B. Harvie of Troy; *Secretary,* Dr. Wisner R. Townsend of New York; *Treasurer,* Dr. Alexander Lambert of New York.

Symposium on Middle-ear Disease.—The evening's session was largely devoted to a symposium on infections of the middle ear, of interest to the general practitioner.

Otitis Media Purulenta; Etiology and Pathology.—Dr. J. E. Sheppard of Brooklyn read this paper. He said the immediate exciting causes of otitis media purulenta were the various forms of pyogenic bacteria. In addition, catarrhal inflammations of the nose and nasopharynx due to colds, influenza, exanthemata, as well as direct irritation due to operative interference, forcible inflation, douches, etc., acted as exciting causes. Among the predisposing cases he mentioned obstructive affections of the nose and throat, hypertrophies, adenoids, exposure to cold, diatheses, lowered resistance of tissue cells, etc. The pathology showed an injection of blood-vessels, swelling of the mucosa, exudation, serous, mucous, and purulent, erosion and ulceration with necrosis of this membrane, rupture of the membrana tympani, bone necrosis in various directions, etc.

Modern Methods of Nonoperative Treatment in Suppurative Otitis Media.—Dr. Edmund Prince Fowler of New York City called attention to the necessity of local treatment in suppurative otitis media and the importance of routine home treatment by the patient or nurse, especially as 98 per cent. of the time patients were out of sight of the surgeon, and must be instructed and provided with means to efficiently carry out orders. The dangers from neglect of faulty treatment and care were dwelt upon and the object of treatment was stated to be not only the abortion, shortening, and cure of the disease, but also the prevention of complications, preservation of function, and of the patient's general health, which latter was liable to suffer from long continued suppurations. The means and methods of promoting an adequate reaction by increasing the hyperemia, leucocytosis, phagocytosis, opsonins, etc., were then briefly recounted. The physical means used were heat, counterirritation, constriction by neckbands, suction, cupping, irrigations, dry treatment, antiseptics, caustics, and blood letting. The author believed that all these had their advantages and disadvantages, and that the best method of using them consisted in combining all, except the caustic treatment and neckband, which, however, he also used, by using his suction bell ear douche, with suitable solutions and temperature. He claimed that by his method all the advantages of the dry and wet treatments were combined, and that their disadvantages were positively removed by irrigating in vacuo, and that the tendency to premature closure of the incision in the drum membrane, and to adhesions, was largely eliminated by his method. Attention was called to the method in detail, and its simplicity, cleanliness, safety, and efficiency were dealt upon. The relief of pain was regularly accomplished without the use of drugs, and even chronic cases did not fail to respond to the treatment.

Dr. Wendell C. Phillips said that the purpose of his paper was to mention the surgical procedures employed in the treatment of acute and chronic purulent otitis media, to outline the indications which necessitated these procedures, and to emphasize their value and results. Bulging of the drum membrane, intense pain and fever, was a syndrome of sufficient import to warrant incision of the drum membrane. It was a safe rule to open the drum membrane as soon as the diagnosis of purulent tympanitis became positive. A clean-cut incision with a long, slender handled, small bladed scalpel, with the patient under nitrous oxide anesthesia, immediately relieved pressure, established drainage, and the subsequent healing of the wound took place with but little damage and no scar tissue. The patient should remain in bed until all acute symptoms had subsided. The most important procedure in intratympanic operations was the removal of polyps or granulation tissue, the most common symptom of which was otorrhea. This tissue was adventitious, and should be removed or destroyed. A simple method of removing large polyps was by means of a small aural snare. Ossiculectomy was an operation by which the drum membrane and ossicles were removed, and was employed as a means of curing chronic purulent otitis media by the removal of diseased tissue and the promotion of drainage and for rendering the tympanic walls more accessible to local treatment. The intratympanic operation was indicated: (1) When a purulent inflammatory process in the middle ear did not respond to local measures of treatment in cases wherein the diseased process was chiefly confined to the drum membrane, ossicles, and tympanic walls. (2) After recurrence of polypiod proliferations, unless such recurrence was associated with evidences of extensive necrosis in the auditus, mastoid antrum, or labyrinth. (3) As a preliminary to the radical operation. Recovery in these cases meant a cessation of the otorrhea. The operation was not wholly without danger. The facial nerve might be injured. The simple mastoid operation was indicated whenever a purulent inflammatory process had invaded the mastoid antrum and mastoid cells with the following indications: (1) Pain over the mastoid region. (2) Tenderness on pressure over the mastoid cortex. (3) Drooping of the posterosuperior canal wall, and bulging of the drum membrane which did not diminish as a result of paracentesis. (4) Fever. (5) Discharge. (6) Subperiosteal postauricular swelling, with or without superficial abscess. The operation was imperative in the presence of symptoms of intracranial complications of purulent labyrinthinitis. (8) the avdent of facial paralysis. (9) Blood examinations in conjunction with other symptoms of mastoiditis was of great diagnostic value. A high leucocytoses and polynuclear percentage indicated the presence of infection in some portion of the body. The mastoid operation in an acute mastoiditis quickly terminated a purulent necrotic process which otherwise might become chronic and attended with all the train of deleterious and dangerous results which accompanied this troublesome affection. To mention them was sufficient: Necrosis of bony areas which were closely related to vital structures; the prolonged and constant danger of serious labyrinthine and intracranial complications; loss of hearing. There were some indications which called for immediate operation, whatever the concomitant symptoms might be, and among these were (*a*) an acute mastoiditis occurring in an ear which was the seat of chronic purulent otorrhea; (*b*) the advent of symptoms of labyrinthitis, the chief of which were nausea, vertigo, and nystagmus; (*c*) the appearance of facial paralysis; (*d*) the appearance of symptoms of intracranial involvement. The results of the simple mastoid operation were the relief of pain, the cure of the destructive purulent process, the preservation of the function of hearing, and it lessened the tendency to serious intracranial and labyrinthine complications, and the possibilities of recurrences were rare. The radical mastoid operation was performed for the cure of chronic purulent otitis media, by which he meant a number of pathological conditions in the middle ear spaces, all having one symptom in common, viz., a persistent otorrhea. The more common conditions producing a persistent otorrhea were (*a*) bone necrosis, confined to various parts of the temporal bone; (*b*) tubercular or

syphilitic bone disease in the temporal bone; (c) purulent inflammatory disease of the lining membrane of the tympanic cavity and its adnexa. Briefly stated, the purpose of the radical mastoid operation was to convert the external auditory canal, tympanic cavity, the attic, aditus ad antrum, mastoid antrum, and the mastoid cells, when diseased, into one wide open cavity, to eviscerate all granulations and diseased bone, destroy all membranous and muscular tissue lying within these limits, including the membrana tympani, and to effect dermatization throughout the entire area, in the hope that by so doing the ramifications of the disease would be terminated. The radical operation was indicated: (1) When a permanent cessation of the purulent process had not been effected by prolonged local intratympanic treatment; (2) when a cure had not been effected by the removal of necrosed ossicles and the curettage of the middle ear; (3) when a sudden cessation of the pus discharge produced chills, fever, vertigo, pain, or other unusual symptoms; (4) when symptoms of mastoiditis supervened in otitis media purulenta chronica; (5) the appearance of facial paralysis during the course of chronic purulent otitis media; (6) attacks of vertigo; (7) in all cases of complicating intracranial or lateral sinus involvement; (8) where there was positive evidence of cholesteatoma in the mastoid antrum; (9) where there were fistulous openings in the cortex of the mastoid process or in the osseous canal; (10) whenever depression or other symptoms of disturbed mentality accompanied the disease. The operation was contraindicated (1) when the purulent process was tuberculous and accompanied by advanced general tuberculosis; (2) in advanced pernicious anemia or albuminuria, and in cachectic diabetes; (3) it was usually contraindicated in young children; (4) in all cases where the disease was confined to the ossicles and tympanic cavity; (5) in adults who had scanty otorrhea without odor, with improper opening on the drum membrane, behind which were retained masses of secretion; (6) in all cases where it was possible to effect a cure by any of the other methods.

The Treatment of Meningeal, Sinusal, and Labyrinthine Complications.—Dr. S. MacCuen Smith of Philadelphia read this paper.

Dr. Arthur G. Root of Albany, Dr. Henry A. Alderton of Brooklyn, Dr. T. Passmore Bereus of New York, Dr. Samuel J. Kopetsky of New York, and others discussed these papers.

Wednesday, January 27.—Third Day.

The Problem of Efficient Nursing for Persons of Moderate Income.—Dr. William O. Stillman of Albany read a paper which dealt with the subject from the standpoint of a practical experiment in educating domestic nurses for their duties by a six months' course of instruction in class and at the bedside. About one hundred lectures, by eighteen to twenty physicians and trained nurses, supplied the didactic part of the course. Quizzes were given on each lecture. The skeleton, manikins, microscope, etc., were used. Careful diet kitchen instruction was given in preparing food. Practical nursing under the supervision of the head nurse was required toward the end of the course.

Report of a Case of Scleroderma, with Exhibition of the Patient.—Dr. Samuel B. Ward and Dr. Erastus Corning of Albany reported this case. The patient was a male, twenty-six years old, married, and a clerk. He was first seen July 23, 1908. The onset occurred two months previous, commencing with stiffness of the hands and feet. There was also a feeling of numbness in the left wrist. This was followed by stiffness and swelling of the left hand, then of the right hand, of both forearms, both feet and legs up to the knee, with edema. The case was now in the atrophic stage and was apparently stationary. The leucocytosis had varied from 11,000 to 22,000, with 35.4 per cent. eosinophiles in the first differential count. Eosinophilia was fully discussed in connection with this case.

Relative Aortic Incompetency of Muscular Origin.—Dr. J. M. Anders of Philadelphia gave a classification of cases of relative aortic incompetency. The present discussion included only cases which were of muscular or neuromuscular origin. These might be placed into three well-defined divisions: (1) Cases of muscular and nervous origin that supervened in the course of fibrous myocarditis and other less serious conditions of the myocardium, independently of valvulitis or advanced changes in the aorta; (2) cases secondary to chronic valvulitis affecting the mitral segments with failure of the left ventricle; (3) cases occurring in the course of or following acute infective diseases due to the action of the specific toxins upon the myocardium. The disappearance of the murmur might coincide with periods of absolute rest; on the other hand, increased activity of the circulation, the result of mental excitement and physical exercise tended to reproduce the murmur. The above views which were extensively supported by clinical and post-mortem observations were also corroborated by the convincing experimental experience furnished by Thayer and McCallum. Dr. Anders reported four illustrative cases.

The Nature of Foot and Mouth Disease.—Dr. Veranus A. Moore of Ithaca read this paper. This disease first appeared in this country in 1870 after the arrival of a shipment of cattle from England to Canada. The great loss sustained was from the loss of flesh and the debilitated condition of the animals, requiring several months for their restoration to health. Among the sequelæ were mentioned abscesses, sloughing of the hoofs, and septicemia. The mortality from this disease among animals was slight, being from 2 to 5 per cent. The symptoms and lesions appeared with such regularity that four stages were well defined by many writers. (1) The dullness and rise of temperature. (2) The appearance of the vesicles. (3) Erosion. (4) Healing. Any practical method of immunizing cattle against the disease had not yet been discovered. Foot and mouth disease which recently appeared in western New York and Pennsylvania was an acute infectious and highly contagious disease affecting large and small animals. Fresh, pure lymph injected into the veins of susceptible cattle produced the disease in quantities as low as .005 cc. Immunity established by one attack of the disease was of short duration. The vesicles appeared on and about the mouth, udder, and feet. The membrane covering them was thin, and soon broke, leaving the epithelial layer attached at the borders. The lesions in the human subject tended to appear in the same locations as in cattle.

The Relation of Ocular and Cardiovascular Diseases.—Dr. Arthur J. Bedell of Albany divided his subject into four heads, and related cases to illustrate each. First, the group in which there was an increased arterial tension without hemorrhage. Second, the group in which there was hemorrhage, but without valvular heart lesion. Third, the group in which there was a definite heart lesion. Fourth, the group in which there were evidences of distinct arteriosclerosis. The eye signs were described and their general significance to the general practitioner pointed out.

Lessons from Physiology and Treatment of Cardiovascular Diseases.—Dr. W. H. Gibson of Utica told of the apparent increase of cardiovascular diseases as noted in general practice, and its actual increase as shown by a study of the vital statistics. Therapeutic measures were useless after degenerative changes had ensued, and the value of preventive measures was suggested by a study

of the cardiovascular mechanism. The arterial changes were considered by him under four heads, viz., the chronic intoxications, as from alcohol, tobacco, the coal tar preparations, etc.; improper diet and overeating; excessive muscular work, and the strain and the stress of modern life. He said that interest in this should be aroused when it was known that 23,000 deaths occurred in one year from cardiovascular diseases, while from tuberculous diseases there were but 17,000 deaths during the same period.

Dr. J. M. Anders of Philadelphia said that a steady increase in the percentage of cardiovascular and renal diseases was noted by all in general practice, and he agreed with the reader of the paper that influenza might have a causative relationship. Another causative factor was the modern overstrain of business life, as well as of social and club life. More physical exercise was required.

Baths and Exercise in the Treatment of Heart Disease.—Dr. Louis Faugères Bishop of New York believed that the benefits derived from exercise and baths in the treatment of heart disease were essentially due to correction of abnormal tension in the blood-vessels and in the heart muscle. Abnormal tension might be low tension or high tension. Throughout the cardiovascular system the muscular elements during life had a certain amount of contraction that existed all the time, and was called "tonus." This tonus was a permanent condition, and was best appreciated by its absolute loss when life ceased. Disorders of the circulation depended upon local or general disturbance of tone, and it was through this disturbance of tone that organic disease of the heart and blood-vessels gave evident symptoms. In valvular disease when compensation failed, there was found a loss of tonicity in the heart muscle leading to dilatation, and a hypertonicity in the blood-vessels leading to contraction. The same condition was sometimes found when toxic substances impaired the strength of the heart muscle. In treatment the removal of the primary cause and the relief of the disorded physiology that had resulted must go hand in hand. The Nauheim-Schott treatment was applicable to all cases in which there was a disturbance of the balance of tonicity between one part of the vascular system and another. When the cause of disease was active, that must first be discovered and removed. Dr. Bishop considered valvular cases, toxic cases, and nervous cases, and cases combining these causes. The valvular cases were those in which the heart valves had been damaged by disease, and in which compensation had been broken. The physician could not, in this instance, remove the ultimate cause of the broken compensation. Broken compensation ordinarily, but not always, consisted of a diminished tone in the heart muscle with a compensatory increased tone in the blood-vessels. The cause of broken compensation might be toxic or nervous, or might have origin in physical strain. In any case, it was necessary to restore the tone of the heart muscle, and to relieve the overtone of the blood-vessels. The patient would often enough be found to have been overloading the system with food, or to have been neglecting systematic exercise, or to have been subject to nervous or physical strain. An intercurrent disease could produce the same result. The symptoms of broken compensation in a valvular case were shortness of breath, swelling of the feet, and congestion and tenderness of the liver. A trip to Germany often removed the cause of the trouble before the patient came under treatment. The vacation, the necessary physical exertion of travel, the possible seasickness, and, at any rate, the irregularities of food, served to unload the system of waste products, to increase various physiological activities, and to remove nerve strain. The Nauheim baths corrected abnormal vascular tone, and relieved the heart of the back strain of contracted blood-vessels and promoted the restoration of the tone of the heart muscle. The resistance exercises through the influence upon the tone of the voluntary muscles, in a greater measure than the baths corrected abnormal vascular tone, and also increased the tone of the heart muscle. The toxic cases of heart disease formed a very important group. They were the cases of patients who had probably been said to suffer from heart symptoms coming from the stomach, while in reality they were suffering from a poisoned heart muscle that had degenerated through toxins of intestinal origin. An examination of many thousand specimens of urine had shown an intimate relationship between indican and albumin in the urine, and between indican and patients suffering from myocardial degeneration. These patients suffered also from damage to the blood-vessels. The first symptoms were irregularities of tonus of various distribution. They must be treated until they were relieved. Going hand in hand with the toxic cases were those of nervous origin. It was perfectly possible for purely mental causes to give origin to hypertonicity of the blood-vessel of sufficient intensity to cause hypertrophy of the heart, high blood pressure, and cardiovascular degeneration. These cases were particularly benefited by the Nauheim-Schott treatment when the patients could go to Germany to get it. This treatment was a system of treating cardiovascular disease that had grown up through the genius and observation of a generation of physicians all over the world. It had many elements, all of which were essential to the complete system. Unfortunately, it had been the custom to minimize the importance of the baths and exercise, because the change of environment was an essential element in the cure. There was no doubt that some patients would improve by the mere change of environment, and it was likewise true that some patients improved by the baths and exercise alone. However, he had defined the Nauheim-Schott treatment as a system, and not as a special remedy, and it seemed that all the elements were qually essential. The treatment could be carried out perfectly well in America by anyone who grasped the essential principles, and was not iron-bound by matters of pure technique. To produce in a patient's home surroundings, an environment of proper mental attitude, the persistent effort to follow up suitable exercise, and the regulation of diet, required an amount of authority, energy, and persistence that few physicians could bring to bear upon these patients in the course of routine medical practice. Hence, the necessity of specialists, and the influence of the "Kur." The reproduction of the saline bath was an easy matter, and trained gymnasts who understood the Nauheim treatment, while rare in this country, could still be found. The author had had this interesting experience that patients who had come from other cities in America for a course of Nauheim treatment in New York which was conducted at a convenient hotel or hospital received as much benefit as they did in going to Nauheim, and with no more labor on the part of the physician than was necessary for the Nauheim physicians themselves. In these cases there was a change of environment, the removal from the place of old habits, and the devotion of the individual to his treatment undisturbed by calls of social and business affairs. In fact, the intelligent patient who subsequently went to Nauheim said that the treatment in New York was at least as efficacious, if not more so. Baths and exercise had a large place in the treatment of cardiovascular disease, but they were not specific remedies, and must be a part of an intelligent general plan. The circulatory organs being the most active organs of physical life, their care must be an important element in the management of all disease. It was the work of the specialist to discover and point out the principles upon which this care must be conducted, and as much as possible to divest the cure of disease of unnecessary

technical details. When the principles were understood, the details followed as a matter of course.

Acute Anemia.—Dr. George W. Crile of Cleveland said that his paper dealt with one of the most ancient of surgical problems, acute or surgical anemia. Either partial or complete anemia had a definite pathology and histology, especially throughout the central nervous system. He spoke of the general circulatory conditions affecting the brain. An increase of hemorrhage increased the pathological tension, and increased still more the effect upon the vasomotor centers. In cases of critical anemia, the patient was partially anesthetized, and operation could be performed with the use of a local anesthetic. If an anesthetic was necessary, a few whiffs of nitrous oxide gas would suffice as a rule. The clinical experience fitted in with the experimental. In complete anemia of the extremities, they could resort to Carrel's technique of end-to-end anastomosis by the suture method. Dr. Crile had performed thirty-two anastomoses between arteries and veins in the human subject, using the radial artery of the donor and a larger vein of the recipient, or vice versa.

The Therapeutic Value of Blood Transfusion.—Dr. W. F. Campbell of Brooklyn read this paper. The object of the operation was to form an anastomosis between individuals. In the selection of the donor, three points should be kept in mind, a preference for the nearest blood relation, a young and vigorous adult, and a thin subject. Dr. Campbell described in detail the operation as performed by Crile, with a few modifications of his own. The indications of direct blood transfusion were dwelt upon. Coagulation of the blood was increased, as well as its oxygen-carrying powers. He related cases in which transfusion appeared to have been of great value. There was no doubt as to the great increase in the numerical elements of the blood following transfusion. There was also an increase in the urea output. It was to be hoped that heterogenous blood might become available. From his own experience the only material to use in transfusion was blood.

Dr. A. T. Bristow of Brooklyn reported a case in which it was shown that the transfusion of blood was far better than the use of saline solution. The patient had received three pints of saline solution and without any good results, and life was only saved by the direct transfusion of blood.

Dr. Alexander Lambert of New York referred to the case of a four-day-old baby suffering from melena who was saved by transfusion of blood. The sight of the marked improvement in the baby as a result of this was quite dramatic.

Dr. Crile said he wished especially to call attention to the great vulnerability of the cerebral cortex to anemia.

Some Congenital Abnormalities of Cervical or Spinal Origin.—Dr. Nathan Jacobson of Syracuse considered three conditions. First, branchial cysts in unusual positions, which he illustrated by reporting two cases, one situated beneath the sternocleoidomastoid muscle and easily removed through an incision parallel with the posterior border of this muscle; the second was a sublingual cyst. The former manifested itself first on the twenty-first day of life; the second was present at birth. The fact that congenital conditions might not develop so as to become annoying until adult life was emphasized. The condition called congenital ranula was considered, and Dr. Jacobson insisted that it was not due to obstruction of Wharton's duct, but was dependent upon either a pathological change in the sublingual gland or, what was more frequently the case than was generally recognized, that it might be of branchial origin, springing from the thyroglossal tract. Secondly, he considered thyroid tumors located in a part of the neck entirely removed and disconnected from the normal thyroid gland. A tumor of this character, and probably malignant, was removed from beneath the sternocleidomastoid muscle. Only seventeen cases of aberrant thyroid tumors were known to have been recorded in medical literature, and in none had a diagnosis been made prior to the operation. Thirdly, he dealt with spina bifida presenting urgent manifestations at birth. A case of spinal meningocele with necrosis of the sac was operated upon when the child was two days old. A perfect result was obtained by operation, and twenty months later the child was in apparently perfect health despite its congenital abnormality.

The Exercise of Descending in the Treatment of Disease.—Dr. Heinrich Stern of New York read this paper.

The afternoon's session was devoted to a symposium on fractures.

Basal Fractures Treated by Subtemporal Decompression.—Dr. Harvey Cushing of Baltimore read this paper.

Some Points in the Diagnosis and Operative Treatment of Simple Fractures.—Dr. Lewis A. Stimson of New York read this paper. The recognition of a complete fracture of a long bone was usually easy. If abnormal mobility and crepitus existed, the diagnosis was readily made. In fracture of the small bones and of the spongy ends of long bones, however, and in one of two parallel and associated bones, and even in fractures of the shaft of a long bone without displacement, both of these signs were frequently unobtainable. The probability of the existence of a fracture could be established by a systematic search for pain, pain on local pressure from without, pain on pressure along the long axis of the bone, and pain when the patient sought to use the affected bone against opposition, and thereby producing a cross-strain. The search for pain on local pressure was best made with the tip of the finger or the rubber end of a lead pencil. In Colles' fracture a well-defined line of sensitiveness could be traced along the radial side and across the dorsum of the forearm just above the wrist; in fracture at the base of the neck of the femur pain was found on pressure behind or in front just inside the great trochanter; in fracture of the surgical neck of the humerus by pressure in front or on the outer side; in fracture of the external condyle of the humerus by pressure on the supracondylar ridge a little above the epicondyle; in fracture of the shaft of a long bone by pressure at the corresponding point on the most accessible side. A necessary precaution to be taken was to carefully support the limb so that the pressure should not move the fragments upon one another. One must not mistake the sensitiveness of a bruise for that of a fracture. Pressure against the ends of a bone in the direction of its long axis caused pain when the bone was completely broken across, but it might fail to do so when the fracture separated a portion of the bone, such as a condyle. In fracture of the ulna, the radius remaining unbroken, pain was caused by asking the patient to extend the elbow in pressing against a fixed object.

Operative Treatment of Simple Fractures.—The reason advanced in favor of the general or extensive adoption of open operation in simple fracture of the shaft of a long bone was that it assured an accurate adjustment of the fragments and its maintenance by suture, and that in this way failure of union and the drawbacks incident to the frequent permanent displacement left by other methods were avoided. Accurate adjustment of the fragments was of no great value unless it could be maintained, and its maintenance by suture or other direct fixation was, at the best, uncertain. The more ardently the surgeon tried to obtain good fixation, the more closely he adjusted the fragments and the more tightly he tied the suture, by just

so much did he add to the probability of a total defeat of his efforts, for he established at the fracture conditions of leverage which went far to insure the immediate breaking of the suture by some one of those slight twists which could not fail to be given to the limb, even during the application of the first dressing to the wound. If the grip of the suture was not slack it would surely break. The value of an adjustment appeared to consist mainly, if not entirely, in the removal of interposed soft parts or small fragments which, if not removed, would delay or prevent reunion or cause persistent deformity. Such removal of possible obstacles to reunion played a rather large part in the arguments advanced in favor of operation, but the percentage of failure of union, in all cases, was small, probably not more than one or two per cent., and in the great majority of these the cause was not the interposition of a removable object. The claim that only by operation could an ideal restoration of form be obtained was one that appealed to the imagination, to the natural desire that the work should be of the highest class and results without blemish. Repair was slower after an operation in which the fragments had been temporarily still further displaced, as had to be done for the placing of a suture. The manipulation necessary in drilling and suturing the fragments delayed union, probably by the additional injury to the periosteum.

Fractures of the Neck of the Femur.—Dr. ROYAL WHITMAN of New York read this paper. He said that his paper was on a technical treatment of fracture of the neck of the femur designed to restore function, and limited therefore to a class of cases in which effective local treatment might be applied. This class was much larger than was indicated by statistics. For it was not generally recognized that the neck of the femur was a weak point in the skeleton and that it might be broken at any age by slight violence. Thus the fracture in early life was often mistaken for hip disease, and in the vigorous adult for contusion or rheumatism. The abduction method was designed to apply surgical principles to the treatment of this fracture, the disregard of which explained the present low standard of success. The patient should be anesthetized and the deformity should be corrected, by rotation and traction if the fragments were separated; by traction, downward pressure on the trochanter, and by the leverage of gentle abduction if the fracture were incomplete. The limb should then be placed in full abduction and securely fixed by a long spica plaster bandage. The advantages of abduction in the treatment of complete fracture after shortening had been overcome by traction were: (*a*) It made the capsule tense and thus aligned the displaced fragments. (*b*) It directed the surface of the outer fragment toward that of the inner. (*c*) It relaxed the muscles whose contraction caused distortion. (*d*) It opposed the trochanter to the side of the pelvis and thus checked upward displacement. In the treatment of incomplete fracture abduction by fixing the neck enabled one by further abduction, aided by traction and pressure, to adjust the shaft in its normal relation to it, and thus to correct deformity without violence or danger of displacement. Fixation in abduction and extension during repair, prevented the contraction which induced flexion and adduction, so often present in cases treated with the limb in the line of the body. Repair after this fracture must be slow, and could hardly be completed within a year, thus prolonged after-treatment was essential to restoration of function.

Radical Conservatism in the Treatment of Compound Fracture.—Dr. MARTIN B. TINKER of Ithaca said that the first essential in the treatment of compound fracture was the successful management of the lacerated and contused wound. The usual methods of treatment were uncertain and illogical. During scrubbing infectious material was often scrubbed into the wound rather than removed, and injured tissues were still further damaged by scrubbing and irrigation with antiseptic solutions and were left to slough. Two methods of dealing with such cases were suggested: (1) In the less severe injuries packing the wound with oiled tampons while the surrounding skin was scrubbed, and later swabbing with some strong, certain disinfectant, followed by excision of damaged tissue and closure as an incised wound. (2) In severe crushes where tissues were pulpified and it was certain that considerable areas would become necrotic, the wound was covered with oiled compresses, the surrounding skin was disinfected, the wound was swabbed with a powerful germicide and dressings applied until the line of demarcation formed. More of the injured part always lived than was expected and a later operation saved all that would prove useful. He advocated the use of local anesthesia and nerve-blocking to minimize shock. An immunizing dose of tetanus antitoxin should be given, in doubtful cases. Blood-vessel anastomosis, bone-grafting, and transplantation, skin-grafting, nerve and tendon suture, should be employed in a wider range of cases than was now usually employed. He presented photographs and radiographs showing an arm saved after being run over by a freight car; also a movable knee after compound, comminuted fracture of patella with soiling of joint cavity as the result of a kick of a horse; a foot saved after car-wheel crush; a useful hand and fingers after gunshot wound, and after buzz-saw injury. There was at present a tendency to neglect common surgical diseases and injuries in favor of the surgery of stomach, pancreas, brain, heart, and other unusual work. Hospital surgeons turned over fractures to internes without personal attention or even instructions. If results were to be improved, surgeons must give their best efforts to compound fractures.

Remote Results Following Excision of the Shoulder Joint for Trauma and Disease.—Dr. CHARLES L. SCUDDER of Boston read this paper, and referred to the conditions for which an excision of the shoulder was to be done, and the uncertainty of the results of an excision in the minds of the profession was emphasized. Many cases were reported and the results given.

Volkmann's Ischemic Paralysis and Contractures.—Dr. R. H. SAYRE of New York said that Volkmann's ischemic paralysis resulted from an undue pressure which was applied to an extremity, usually in the treatment of fracture. The inflammation of the muscles which resulted caused subsequent fibroid degeneration with marked contraction. Efforts to restore the vitality by means of massage and electricity had proven almost universally useless; therefore, operative procedures had been adopted.

A Case of Leukemia with Unusual Blood Findings.—Dr. H. G. WEBSTER of Brooklyn reported the case of a woman who gave a history of rheumatoid pains and progressive loss of flesh and strength for three years. The blood picture, on thorough examination, was that of myelogenous leukemia. Under treatment there were rapid changes to the lymphatic type, and then a gradual restitution to the normal. The subsequent development of the painful osseous tumors proved to be syphilitic.

New Plastic Operation for Cicatricial Palatopharyngeal Contractures and Adhesions.—Dr. JOHN O. ROE of Rochester told of the frequency of cicatricial contractures or occlusions of postnasal space resulting from ulceration or traumatism, as well as the difficulties encountered in the attempts at relieving the conditions because of the persistence with which the adhesions recurred. The permanent relief of the condition followed new plastic operations for covering the opposing raw surfaces, after the liberation of the adhesions, by mucous membranes taken from the neighboring parts.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Nineteenth Regular Meeting, Held December 11, 1908.

The Secretary, Dr. J. S. Thacher, in the Chair.

Facial Nevus Treated by Radium.—Dr. Robert Abbe showed this patient, a young woman, who came to him in the spring of the present year with an extensive nevus occupying the eye, nose, lip, cheek, and right temporal region. Under one treatment with radium the temporal part was nearly cured, the red areas giving place to patches of white skin that were velvety to the touch and quite normal in appearance. The advantage of radium over other methods consisted in the prevention of scars, such as were formed when the old method of treatment by means of the cautery was used. Radium sealed in a glass tube was used in this case, being moved over the entire surface, pressing for ten minutes on each successive spot covered by the little tube. Some tumefaction followed the application of radium, the symptoms of reaction continuing for two or three weeks. After this subsided normal white skin appeared at the areas that had been exposed to the action of the salt. Slight atrophy of the skin might result from the cured vascular tissue, but cicatricial tissue was never formed unless the application was overdone. Dr. L. Wickham of Paris had substituted a plaque for the radium tube, more even exposure being possible with the use of the former appliance. The plaque simply consisted of very strong radium mixed with varnish and spread over an even surface. Whether the tube or the plaque was used, the dosage should be carefully graduated; too long an exposure to the action of the salt resulted in atrophy of the skin; too little did not produce any curative effect. No untoward symptoms from any neighboring organs, such as the eyes, had been noted in exposing the temporal patch of nevus to the action of the radium salt.

Bone Pegs in the Treatment of Fractures of the Femur.—Dr. Abbe presented this patient, a scene shifter in a theater, who had both his femurs broken at the neck by the falling of a piece of scenery on his back while he was in a kneeling position. The case seemed hopeless so far as the attaining of good functional results were concerned. The use of bone pegs to hold the fractured parts was decided upon, and surprisingly good results were obtained with this technique. The patient recovered all the functions of the hip joint and could walk, run and jump with ease. The technique of using the pegs was very simple. Large pencil-shaped pieces of ox thigh bone were shaped and, after being sterilized, were simply driven through the broken parts, a small incision through the skin being all that was necessary to prevent laceration. The cancellous tissue of the femur offered but little resistance, so that no drilling of holes was necessary. An *x*-ray picture showed the peg in position, reaching horizontally through the trochanters and neck well into the head of the bone; a second picture, taken six months later, showed partial absorption of the pegs, their outlines being indistinct. It was probable that complete absorption would result within one year's time. The use of bone pegs had been followed by much better results than had been previously attained in similar cases with the use of screws and nails of metal. Any animal bone might be used to serve the purpose of pegs. A toothbrush handle, properly shaped and sterilized, had been successfully used once by Dr. Abbe.

Dr. Joseph D. Bryant said that the results in the case presented by Dr. Abbe were very good indeed, but heretofore failure had attended the use of metallic pegs in this connection in the majority of instances, so much so that the inclination to employ them had not kept pace with the opportunity. The technique employed by Dr. Abbe, namely, the driving in of the bone peg through a small skin incision, was much better than the making of a deeper incision for the purpose, for obvious reasons. It was important to remember, in his opinion, that impacted fractures should not be broken up because of the fact alone of impaction, but only when as the result of the impaction ungainly or obstructive deformity arising therefrom could be corrected or made less objectionable. The notion that impacted fractures of the neck of the femur should be broken up because of the fact of impaction, and treated thereafter by any accepted method, was not sustained by the common results which the treatment of the unimpacted fractures by the best of means appeared to secure. He had in mind two cases of impacted fractures now under his charge in Bellevue Hospital, with no appreciable deformity but shortening. These fractures were going on to perfect recovery after three and five weeks' time respectively. The diagnosis in both instances was confirmed by *x*-ray plates.

Leukemia in Advanced Years.—Dr. A. A. Smith read this paper (see page 169).

Dr. L. A. Conner said that the blood picture in the second case described by Dr. Smith was a very unusual one for leukemia. The great number of polynuclear leucocytes with the small percentage of lymphocytes would make him hesitate in classing this case as a primary disease of the blood.

Dr. Smith said that he examined the patient very carefully for signs of malignant disease that could account for the blood picture, but could discover none whatever. No viscus was enlarged in this patient with the exception of the spleen, which was felt distinctly about three and one-half inches below the free border of the ribs during quiet breathing. He was, of course, familiar with the doubts expressed in such cases, but as he saw the patient only once, he could add nothing more to the statements in his paper except to repeat the fact that the blood examinations were in every case made by very competent observers. The special point, however, that he tried to bring out in his paper was the advanced age of all three patients. He would like to know whether any of the members had ever had cases of leukemia under observation in persons of advanced age.

Dr. Kinnicutt said that he had never seen a case of leukemia in a person of advanced age.

Importance of Laryngeal Examinations in Early Pulmonary Tuberculosis; also, of the Probable Presence of Malaria without Organisms Being Discovered.—Dr. Robinson said that within the last three weeks he had two patients come to him for examination and diagnosis who had symptoms and signs which indicated possibly pulmonary tuberculosis. In neither case, however, did microscopic examination show any tubercle bacilli. In the first case, seen previously on two occasions by a prominent practitioner of New York, a diagnosis of a dilated bronchus had been made. In the other case, no positive diagnosis was made other than cough with expectoration. There was no hoarseness, no dysphagia; hence, probably, the larynx had not been examined in either case. Upon laryngeal examination of the first case referred to, Dr. Robinson found already beginning infiltration and edema of the epiglottis, which to him meant indubitably beginning laryngeal tuberculosis, and pointed almost with certainty to tuberculosis being present in the lungs. In the second case was an area of redness, with slight vascularization of the left vocal cord, and also redness of the posterior surface of the epiglottis. The left vocal cord was also slightly sluggish in approaching the median line during phonation. The rest of the larynx was possibly paler than normal. In this case the intralaryngeal appearances made the diagnosis both of the beginning

laryngeal tuberculosis and pulmonary tuberculosis probable. In some such cases the intrapulmonary disease might grow worse and the intralaryngeal disease remain almost stationary during many months, and sometimes, even though no local treatment had been used. Indeed, the local laryngeal symptoms were always slight, if any, in the cases referred to, they did not direct special attention to the larynx. In these instances he regarded the intralaryngeal appearances as especially important from the point of view of an early diagnosis. Personally, Dr. Robinson believed that the outcome both of laryngeal and pulmonary disease at this stage was notably helped by suitable inhalations persistently and properly used.

Dr. Robinson had another patient whose history and symptoms, with the addition of a considerably enlarged spleen, seemed to show malarial poisoning. The blood was carefully examined microscopically, but no malarial organisms were found. Chilly feelings, general malaise, and notable disturbances of temperature, apparently promptly disappeared with frequent and rather large doses of cinchona bark, and after other remedies had proved useless. Were such cases malarial? Dr. Robinson had observed them not very infrequently among adults, and more frequently among children. Very rigid, careful searching of the blood microscopically, before quinine or bark had been taken, had several times resulted negatively, so far as the finding of the plamadium is concerned. The examinations of the blood were made by skilled and reliable observers with the best microscopes. The importance of the recognition of malarial poisoning, despite negative microscopic research, and in view of rapid and manifest benefit from the use of quinine or bark, seemed to him to make a diagnosis by exclusion proper, especially when the symptoms previously manifested, such as chilly feelings, malaise, lassitude, and intermittence not infrequently, pointed in that direction. Influenza, gastric catarrh, ephemeral fever, etc., did not satisfy his mental requirements. Again, he was not satisfied always as to his ultimate diagnosis in difficult or obscure cases, with the use of quinine even in large doses, and mainly because he had known quinine to fail utterly at times to relieve or cure malaria, although the malarial organisms had been seen repeatedly.

Dr. Robinson said further that he would add a word to what he had previously written, about the great importance of a laryngeal examination to fix a doubtful diagnosis of pulmonary tuberculosis, and it was strange how frequently this examination was still ignored by men who were careful and well informed, and who were considered to be specialists in this dread disease.

An Interesting Microphotograph of the Kidney.—Dr. L. B. Bangs showed microphotographs of the kidney, of the liver, and of the lung. The special interest attached to them consisted in the fact that the person to whom these organs belonged died in the year 1792 and was exhumed 113 years later, when a partial autopsy was performed and several organs prepared for microscopical examination. The members of the society had, of course, guessed that the body was that of Paul Jones. The photographs were of further interest because they enabled the diagnosis of the pathological condition to be made so many years after death. The wonderful preservation of the parts was probably due to the method of burial used in the case of Paul Jones. His body was placed in a leaden coffin, which was then filled with alcohol through a small opening left at the head of the coffin. This opening was then sealed, so that the body was really buried in an hermetically sealed coffin filled with alcohol. The body was exhumed in 1899, the autopsy being performed by Professor Cornil and his assistant, showing death to have been caused by chronic nephritis. The biography of Paul Jones tells of a chronic cough from which he suffered during the later years of his life, and it was of interest to note that unmistakable evidences of a tuberculosis of the lungs were found by Professor Cornil; no tubercle bacilli could be found, however, the search only revealing the presence of crystals of tyrosin in parts of the lung tissue. A remarkable fact was the close resemblance of the features in the well-known bust of Paul Jones Houdon to the original; indeed, this resemblance helped very materially in the identification of the body. Dr. Bangs showed photographs of this bust and of the face of the exhumed body. The resemblance between the two was very striking; moreover, a composite picture made of the two showed the agreement of almost every line in the work of the sculptor with the features of the original.

Meningococcus Septicemia.—Dr. F. C. Kinnicutt reported this case. It occurred in his service in the Presbyterian Hospital, and was of such interest that it would be reported in full, with a review of the literature, by Dr. Bovaird, in the forthcoming volume of the "Transactions of the Presbyterian Hospital." The question of a primary meningococcus blood infection had been a subject of much discussion, Dr. Kinnicutt said, and in a recent review of the subject, with a report of a case of meningococcus septicemia occurring in the Montreal General Hospital, Duval stated that there was no authentic case where the meningococcus had produced lesions outside of the meninges, in the absence of a preexisting meningitis. Since the publication of Duval's paper Dr. Bovaird had found two cases in the literature, one reported in 1906 by Andrews, pathologist to St. Bartholomew's Hospital, London, and one by Liebermeister in October, 1908, which, Dr. Kinnicutt said, must be accepted as cases of primary meningococcus blood infection without meningeal inflammation. A review of the literature also showed that the meningococcus had been isolated from the blood in a comparatively small number of cases; that in almost every instance where the organism had been found in the circulating blood there had been a fatal issue and the body had shown various associated lesions, viz., of the joints, anterior chamber of the eye, of the pericardial, endocardial, and pleural cavities. Hypopyon iritis had been reported in only four cases, to which must be added the present case. The case of meningococcus occurring in Dr. Kinnicutt's service furnished the following points of interest: (1) The meningococcus was recovered from the blood in pure culture. (2) The symptoms from the beginning were those of a general infection. There were very abundant and widespread hemorrhages, varying in size from a pinhead to 2 cm. in diameter, cutaneous and into the mucous membranes, the affection of a large number of joints, and a severe hypopyon iritis. There was a rapid superficial sloughing of a large proportion of the cutaneous extravasations and of those in the buccal cavity. The cerebrospinal fluid was under normal pressure and was either clear or slightly blood-tinged, and the smears showed only red blood cells, and these only in the blood-tinged specimens. It gave sterile cultures from all the lumbar punctures made at various stages of the disease. Ninety c.c. of cerebrospinal fluid was removed at different times. (3) The symptoms of a meningitis consisted in a moderate stiffness of the neck, occurring rather late in the disease, and Kernig's sign of very temporary duration. (4) The very rapid improvement in all symptoms following the use of Flexner's serum, given once 20 c.c. by the intradural method, followed directly by the intravenous injection of 25 c.c., and twenty-four hours later by 30 c.c. given subcutaneously, and once again after seventy-two hours, 30 c.c. subcutaneously. (5) Complete recovery, with the exception of loss of sight in one eye, due to detachment of the retina either by hemorrhage or other retinal exudate. Doctor Kinnicutt, in conclusion, said that although the dominating symptoms from the beginning of the ill-

ness were those of a grave blood infection, and the cerebrospinal fluid gave no signs of a meningeal inflammation, the recovery of the patient did not permit him to go further than to report the case as one of meningococcus septicemia with a sterile cerebrospinal fluid.

Dr. M. Allen Starr said that the case reported by Dr. Kinnicutt was of special interest to him, because he was called to see a patient two weeks ago who presented a picture very similar to that described by Dr. Kinnicutt. His patient was a girl of sixteen, who developed symptoms of cerebrospinal meningitis after having gone through an attack of measles. Dr. Starr saw the child on the fifth day of the disease, and at that time the picture of meningitis was unmistakable; paralysis, hypersensitiveness, Kernig's sign, etc., were all present. A lumbar puncture was done and 11 c.c. of cerebrospinal fluid obtained; this was, however, pronounced sterile after an examination in the laboratory of Dr. Flexner at the Rockefeller Institute. The patient remained in about the same condition for a week, when a second lumbar puncture was performed; this time, too, the fluid proved to be sterile. In view of these findings Dr. Starr did not feel justified in using the antimeningitis serum of Flexner, because the indication for the latter would seem to be the presence of diplococci in the spinal fluid. Huss's serum was tried in the case, and the employment of it was followed by a fall of temperature from 100°-102° to 99°, by some relaxation, and by improvement in the mentality of the patient. He would like to know what course one should take in such a case in reference to the use of the Flexner serum. Dr. Flexner was appealed to in reference to this point, but was unwilling to recommend the use of the serum in such a case.

Dr. Kinnicutt said that in his opinion the serum should not be used unless the meningococcus was discovered in the spinal fluid or recovered from the blood of the patient. In the case reported by him the second condition was present, which, of course, called for the use of the serum. As there were no extrameningeal symptoms in Dr. Starr's case, one could suppose that no septicemia existed, though only a blood culture could settle this point. In his case, immediately on the recovery of the meningococcus from the blood the serum was given, both subcutaneously and by the intradural method, within the period of an hour. In the absence of the organism in the cerebrospinal fluid obtained by lumbar puncture, the serum was not again introduced into the spinal canal, but was given subcutaneously and injected directly into a vein.

Dr. L. A. Conner said that the negative examination of the spinal fluid and the whole picture of the disease as described by Dr. Kinnicutt did not, in his opinion, exclude the possibility of cerebrospinal meningitis. The small amounts of spinal fluid obtained might have been due to the occlusion of the foramen of Magendie, and it occasionally happened, even in acute cases, that the organisms could not be recovered from the spinal fluid. That a meningococcus septicemia, such as this case had been proved to be, could be recovered from was a fact of extreme interest and importance.

Dr. Kinnicutt said that the possibility suggested by Dr. Conner naturally was considered, as cases had been reported in which a fibrinoplastic exudate in the neighborhood of the fourth ventricle had effectually closed the outlets for ventricular fluids; it was believed, however, to be improbable that such large amounts of cerebrospinal fluid could be obtained by lumbar puncture as had occurred in his case (90 c.c. altogether, flowing under about normal pressure) if the foramen of Magendie had been sealed.

Dr. J. S. Thacher asked Dr. Kinnicutt whether the striking cerebral symptoms in the patient did not indicate the presence of meningitis.

Dr. Kinnicutt said that the patient was stuporous only during the first few hours after admission to the hospital. After twenty-four hours the mind of the patient seemed quite clear. Moreover, there was no stiffness of the neck at first, both this and Kernig's sign having appeared much later in the development of symptoms. On the other hand, the systemic symptoms were the striking feature of the case from the beginning, and were explained by the recovery of the meningococcus from the blood of the patient.

Dr. Joseph D. Bryant said that one path of communication of the cerebrospinal fluid and the systemic blood had not been mentioned by previous speakers, viz., that of the longitudinal sinus into which it directly entered after reaching the surface of the brain. In these circumstances the infected fluid could mix with the blood in which germs would be found, while absent in the fluid of the spinal cord because of closure of the foramina of Magendie and of Luschka. Perhaps this might have been the path of blood infection in the case under consideration. Possibly, also, that of Dr. Starr might have been influenced by this means.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Texas State Board of Medical Examiners.

Dallas, November 10, 11 and 12, 1908.

ANATOMY.

1. Describe the tibia and name the muscles attached.
2. Describe the collateral circulation around the knee.
3. Describe the kidney.
4. Name the muscles of the femoral region.
5. Give subdivision of the large intestines and source of blood supply to each.
6. Give origin, course and distribution of the ulnar nerve.
7. Give origin, course and distribution of the radial artery.
8. Give the origin, course and distribution of the dorsalis pedis artery.
9. Describe Hunter's canal, naming the structures found therein, and their relation to each other.
10. What structures would you cut through in an amputation at the middle of the humerus?

HISTOLOGY.

1. Give the divisions of the urethra and give histology of the prostatic portion.
2. What is the pelvis of the kidney?
3. Describe nonstriated muscular tissue and name its principal locations in the body.
4. Give histology of arteries, veins and capillaries.
5. Name the tunics of the eyeball and give its refractive media.
6. Describe a lobule of the lung.
7. For description the olfactory organ is divided into three regions; name them, and give histology of the Schneiderian membrane.
8. Name the three divisions of ear, and the bones of the middle ear.
9. Describe the musculature of the uterus.
10. Describe the mucosa of the stomach.

PHYSIOLOGY.

1. Name the glands secreting the saliva.
2. Give specific gravity, chemical reaction, and physiological reaction of saliva.
3. Give name, origin, distribution, and function of the fifth cranial nerve.
4. Where are the following cerebral nerve centers: (*a*) saliary, (*b*) visual, (*c*) respiratory, (*d*) mastication, and (*e*) micturition?
5. Given an exposed artery and vein in the living subject, how would you distinguish them without reference to anatomical landmarks?
6. What portion of the spinal cord is affected (involved) in locomotor ataxia?

7. Describe the physiologic functions of the kidneys.
8. Name the four divisions of the circulatory system and describe the circulation of the blood.
9. Describe the portal circulation; name vessels carrying the blood to and from the liver and into what does the latter empty?
10. Define (*a*) hyperopia, (*b*) heterophonia, (*c*) euthanasia (*d*) myopia, (*e*) necremia, (*f*) hydremia, (*g*) diopter, (*h*) aphasia, (*i*) astigmatism, (*j*) chyluria.

CHEMISTRY.

1. Describe the chemical change in starch during digestion.
2. Describe oxygen.
3. What are the symptoms of acute arsenic poisoning?
4. Give chemistry of respiration.
5. Give the chemical formula for alcohol; for ether.
6. To what salts do most cathartic mineral waters owe their virtue?
7. Give two chemical tests for albumin in the urine.
8. Give two chemical tests for sugar in the urine.
9. Give the formula and properties of chloroform.
10. Define an alkaloid and name several used in medicine.

BACTERIOLOGY.

1. Name and give classification of fungi that are connected with diseases in man.
2. Name chief forms of bacteria.
3. Name the most important surgical microorganisms, *i.e.*, those most frequently met with in surgical work.
4. What bacteria are likely to be mistaken for the tubercle bacillus, and how may this error be avoided?
5. Describe ptomains and name three sources of ptomain poisoning.
6. Give detailed description of Widal's microscopical test in typhoid fever.
7. Name and describe a malarial parasite.
8. Define (*a*) phagocytosis, (*b*) chemotaxis, (*c*) opsonin.
9. State accurately the steps you would take to stain, mount and examine a specimen of sputum from an advanced case of tuberculosis.
10. Define (*a*) aërobic, (*b*) anaërobic, (*c*) diplococci.

PATHOLOGY.

1. What are the pathological changes that take place in the blood in malarial fever?
2. Lobar pneumonia; name its different stages and describe each.
3. Describe the characteristic lesions of typhoid fever.
4. Pathology of emypema.
5. Pathology of erysipelas.
6. Pathology of acute gastroenteritis.
7. Pathology of diphtheria.
8. Describe union by first intention; describe union by second intention.
9. Hernia—Name three varieties of external hernia, and give usual contents of the sac in oblique inguinal.
10. What is the pathology of rheumatism?

PRACTICE OF MEDICINE.

1. Give diagnostic significance from topographical occurrence of edema.
2. State clinical significance of arrhythmia (irregular pulse), and its principal varieties.
3. Describe symptoms of aneurysm of ascending aorta.
4. Differentiate between acute pericarditis, acute endocarditis, and acute myocarditis.
5. Differentiate between acute pneumonia and exudative pleuritis.
6. Differentiate between hypertrophy and dilatation of heart.
7. Differentiate between acute miliary tuberculosis and enteric fever.
8. State symptoms of gastroptosis.
9. Discuss acute yellow atrophy of liver.
10. Differentiate carcinoma of stomach and chronic pancreatitis.

OBSTETRICS.

1. Describe fertilization of the ovum.
2. Describe the placenta and give its functions.
3. Give normal duration of pregnancy and method of calculating duration.
4. Give some of the most reliable signs of pregnancy.
5. Differentiate between a first and a subsequent pregnancy as regards changes in the uterus.
6. Give causes of vomiting in pregnancy.
7. What conditions in pregnancy are dangerous to the life of mother and child?
8. Define placenta previa; classify, and give treatment.
9. What is the significance of albuminuria in pregnancy? And give treatment.
10. Name some conditions which might complicate pregnancy or be mistaken for it.

GYNECOLOGY.

1. Give blood supply, and nerve supply, and lymphatics of the womb and ovaries.
2. Define kraurosis vulvæ.
3. Give cause of inversion of the uterus, its diagnosis.
4. What are symptoms, and cause of pudendal hematocele?
5. What is caruncle of the urethra?
6. Give differential diagnosis of tuberculous and gonorrheal cystitis.
7. What are the causes of pelvic peritonitis?
8. Give differential diagnosis of acute salpingitis, oöphoritis, and appendicitis.
9. What is pathology of (*a*) hydrosalpinx, (*b*) hematosalpinx? Give diagnosis.
10. What is acute parametritis? Give its etiology, pathology.

SURGERY.

1. What is an aneurysm?
2. What is a fracture?
3. What is a contused and lacerated wound?
4. Describe Colles' fracture and give treatment.
5. What is your treatment in Pott's fracture?
6. Describe an amputation of lower third of thigh.
7. How would you treat a case of wry neck?
8. What is fistula in ano, and how treat it?
9. Describe technique of appendectomy.
10. Give symptoms and operative technique for gallstones.

HYGIENE.

1. Mention and describe the diseases of animals that are communicable to man, and state the means that should be employed for the prevention of these diseases in man.
2. What are the alimentary principles of food, their functions, the object of cooking food?
3. What is the object of clothing, its virtue in different seasons; with reference to material, color, texture, and hygroscopic quality?
4. Give the best methods of disinfecting a room and contents after exposure to the contagion of smallpox.
5. When are diseases said to be "epidemic," "pandemic," "endemic"?
6. Classify the following diseases, whether contagious or infectious: typhoid fever, typhus fever, cholera, scarlet fever, smallpox, yellow fever. Give method of stamping them out.
7. What is the difference between fermentation, oxidation, and putrefaction?
8. What deleterious gases accumulate in an imperfectly ventilated schoolroom? State amount of fresh air required per minute for each child. Also state the evil effects from inhaling air rendered impure by respiration.
9. Define ptomain. Give sources of origin and describe their agency in inducing diseases and give the symptom produced by them.
10. How would you guard against the bowel disturbance of infants during their first and second summers?

MEDICAL JURISPRUDENCE.

1. What is meant by last sickness, and what are its relations to the law?
2. How may human hairs be distinguished from fibers or the hair of the other animals?
3. What are the most important questions arising in connection with gunshot wounds?
4. What is the cause of death following burns?
5. How is it possible to distinguish false from true pregnancy?
6. How do you distinguish between injuries to the head, produced during delivery by accident, and those made with criminal intent?
7. What is meant by the age of consent?
8. What is meant by the expectation of life?
9. Describe the coroner system.
10. What is a wound and what are the most important questions that arise in connection with wounds?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

TEXAS STATE BOARD OF MEDICAL EXAMINERS.

Dallas, November 10, 11, and 12, 1908.

ANATOMY.

2. *The arterial anastomosis about the knee-joint* is formed as follows: (1) *The superior external articular artery* anastomoses with the descending branch of the external circumflex, the inferior external articular, the anastomotica magna and the superior internal articular. (2) *The superior internal articular artery* anastomoses with the anastomotica magna, the inferior internal articular, and the superior external articular. (3) *The inferior external articular artery* anastomoses with the inferior internal articular, the superior external articular, and the anterior recurrent branch of the anterior tibial. (4) *The inferior internal articular artery* anastomoses with the inferior external articular, and the superior internal articular. *The whole* forms a superficial and deep plexus; the former being situated between the fascia and skin round the patella, and the latter on the articular surfaces of the lower end of the femur and the upper end of the tibia.

4. *Muscles of the femoral region*, are: Tensor vaginæ femoris, Sartorius, Quadriceps extensor femoris (Vastus externus, Vastus internus, Rectus femoris, Crureus), Subcrureus, Gracilis, Pectineus, Adductor longus, Adductor magnus, and Adductor brevis.

5.

SUBDIVISIONS OF LARGE INTESTINES.	ARTERIAL SUPPLY.	BRANCH OF
Ileocecal valve, Cecum, (Appendix)	Ileocolic and Right colic	Superior mesenteric
Ascending colon	Right colic	
Transverse colon	Middle colic	
Descending colon	Left colic	
Sigmoid flexure	Sigmoid	Inferior mesenteric
	Superior hemorrhoidal	
Rectum	Middle hemorrhoidal	Internal iliac
	Inferior hemorrhoidal	Internal pudic

9. *Hunter's canal* occupies the middle third of the thigh, beginning at the apex of Scarpa's triangle, and extending to the femoral opening in the Adductor magnus muscle. It is bounded *externally* by the Vastus internus; *internally* by the Adductors longus and magnus. It is covered in by a fibrous expansion from the Vastus internus to the Adductors; over this roof lies the Sartorius. It contains the femoral artery, and femoral vein, in a sheath; and the long saphenous nerve outside the sheath. The vein is behind and external to the artery; the nerve is at first external to the vessels, then it crosses over them.

10. *Structures cut in an amputation at the middle third of the humerus*, are: Skin; fascia; muscles: biceps, coracobrachialis, brachialis anticus, triceps; arteries: brachial, superior profunda, inferior profunda; veins: basilic, cephalic, brachial, superior profunda, inferior profunda; nerves: median, ulnar, musculo-spiral, internal cutaneous, musculo-cutaneous; bone: humerus.

PHYSIOLOGY.

1. *The glands secreting the saliva*, are: The parotid, submaxillary and sublingual glands (and the small mucous and serous glands of the mouth).

2. SALIVA. *Specific gravity:* about 1002 to 1006. *Chemical reaction:* Alkaline. *Physiological reaction:* Through the ptyalin which it contains, it begins to convert starch into maltose.

3. FIFTH CRANIAL NERVE. *Name:* Trigeminal, or trifacial nerve.

Origin: (1) *Superficial*—from the side of the pons varolii; (2) *Deep*—from the medulla, and the floor of the fourth ventricle.

Distribution: First, or ophthalmic branch, to conjunctiva, and skin of upper eyelid, cornea, skin of forehead, and nose, lachrymal gland, and skin of nose. *Second, of superior maxillary* branch, to skin and conjunctiva of lower eyelid, nose, cheek, upper lip, upper teeth, and palate. *Third, or inferior maxillary branch*, to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, and skin of lower part of face. Also to muscles as indicated under *Function*.

Function: It supplies sensation to all the parts mentioned above; but, in addition, the *Inferior maxillary branch* supplies motion to the muscles of mastication (Masseter, Temporal, External, and Internal Pterygoids), and the Mylohyoid, and anterior belly of the Digastric.

4. (*a*) The *salivary* center, is in the medulla; (*b*) *visual* center, is in the occipital lobes; (*c*) *respiratory* center, is in the medulla; (*d*) center for *mastication*, is in the medulla; (*e*) center for *micturition*, is in the lumbar enlargement of the spinal cord.

5. *Arteries* are recognized by: (1) their pulsation, when no proximal constriction is used; (2) their swelling proximally when compressed distally (where no constrictor is used); (3) their firm, round, resisting, elastic, cord-like feeling; (4) their peculiar sensation when compressed between the fingers, presenting a central depression and two lateral, elevated ridges; (5) their thicker walls; (6) their rubber-tube-like feeling when touched and tendency to glide from beneath the fingers; (7) the force required to compress them; (8) their regular outline; (9) their pinkish or pinkish-yellow color.

Veins are recognized by: (1) not pulsating (where no Esmarch is used); (2) by having thinner coats; (3) by swelling toward the periphery when compressed centrally (no constrictor being used); (4) by being softer and less resisting to touch; (5) by the flat, ribbon-like feeling throughout their whole width when compressed between the fingers; (6) by their purplish color; (7) by their wavy, irregular contour; (8) by their accompanying the arteries, in many regions, in pairs or companion veins; (9) by their larger size than the corresponding arteries; (10) by the ease with which they are compressed. (From Bickham's *Operative Surgery.*)

6. The posterior columns of the spinal cord are involved in locomotor ataxia.

8. The four divisions of the circulatory system, are: (1) The heart; (2) arteries; (3) capillaries, and (4) veins.

9. The vessels that carry blood to the liver, are the hepatic artery and the portal vein; the vessels that carry blood from the liver, are the hepatic veins, which empty into the inferior vena cava.

10. (*a*) *Hyperopia* is a condition in which the anteroposterior axis of the eye is abnormally short, and parallel rays are focused behind the retina.

(*b*) *Heterophoria* is a condition in which the visual axes of the eyes tend to deviate.

(*c*) *Euthanasia* is painless and easy death.

(*d*) *Myopia* is a condition in which the anteroposterior axis of the eye is abnormally long, and parallel rays are focused in front of the retina.

(*e*) *Necremia* is death of the blood.

(*f*) *Hydremia* is a watery condition of the blood.

(*g*) *Diopter* is the unit of measurement for refractive power; it represents the refractive power of a lens at a focal distance of one meter.

(*h*) *Aphasia* is loss of the power of expression by speech or writing.

(*i*) *Astigmatism* is a condition in which owing to a greater curvature of the eye in one meridian than in others, the refractive power of the eye varies.

(*j*) *Chyluria* is a condition in which the urine appears to be milky, from the presence of fat.

CHEMISTRY.

1. During digestion, starch (by means of the ptyalin of the saliva, and the amylopsin of the pancreatic juice) is converted into dextrin and maltose. The dextrin is afterward converted into maltose also.

2. OXYGEN is a colorless, odorless, tasteless gas, heavier than air, slightly soluble in water, has an intense affinity for other elements, combining with almost all of them except fluorine. It is necessary to life, and is a supporter of combustion. It occurs free in the air and in combination in water, rocks, minerals, etc. It is more abundant than any other element, forming about 40 per cent of the total weight of the earth.

3. The *symptoms of acute arsenical poisoning* "In acute cases the symptoms usually begin in from twenty to forty-five minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green (Paris green). Purging. More or less severe cramps in the lower extremities." (Witthaus' *Essentials of Chemistry.*)

4. The chemical changes produced in the *air* by respiration are:

	INSPIRED AIR.	EXPIRED AIR.
Oxygen	21 per cent.	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide...	0.04 per cent.	4.4 per cent.
Other gases.....	Rare.	Often present.
Watery vapor.....	Variable.	Saturated.

In the *blood* the chemical changes are: (1) The giving up of the CO_2 by the venous blood; (2) the absorption of oxygen during inspiration, and (3) the blood loses a small amount of watery vapor.

5. The chemical formula for *alcohol,* is C_2H_5OH; for *ether,* is $(C_2H_5)_2O$.

6. Most cathartic mineral waters owe their virtue to the following salts: Magnesium sulphate, sodium sulphate.

7. TWO TESTS FOR THE DETECTION OF ALBUMIN IN THE URINE: "The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent, it is to be treated with a few drops of magnesia mixture and again filtered."

I.—*The heat test:* "The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3."

II.—*Heller's modification of the nitric acid test:* "Place in a test-tube a layer of HNO_3 about 2 centim. in thickness; then, with a pipette carefully float upon the surface of this a layer of the urine in such a manner that the liquids do not mix. If albumin be present, a cloudy ring appears *at* the point of junction of the two layers, the borders of the cloud being sharply defined. A cloudy ring may be formed by the presence of an excess of urates, but in this case it is not *at,* but *above,* the point of junction of the layers, and its upper border is not sharply defined, but fades off gradually." (Witthaus' *Essentials of Chemistry.*)

8. TWO TESTS FOR THE DETECTION OF SUGAR IN THE URINE: The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

(1) *Fehling's test:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(2) *Boettger's test:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by the dark or black color of the bismuth powder, the litharge retaining its natural color. (From Witthaus' *Essentials of Chemistry.*)

9. CHLOROFORM. *Formula:* $CHCl_3$. *Properties:* It is a colorless liquid, volatile, with a sweet taste, and agreeable odor. It is heavier than water; is a good solvent for fats and other substances; it mixes with alcohol, and ether, but not with water.

10. An *alkaloid* is a basic nitrogenous substance of alkaline reaction and capable of combining with an acid to form salts in the same way that ammonia does.

Several alkaloids used in medicine: Strychnine, quinine, cocaine, atropine, morphine, codeine, pilocarpine, apomorphine, aconitine, eserine.

BACTERIOLOGY.

1. The fungi which are connected with diseases in man, are:

(1) The Blastomycetes, or yeasts.
(2) The Hyphomycetes, or moulds; and
(3) The Schizomycetes, or bacteria.

2. The three basic forms of bacteria are: (1) The *coccus,* which is round or oval, and may appear singly, in pairs, in groups of four, in chains, or in bunches. (2) The *bacillus,* which is rod shaped, with the longer sides parallel, and the short ends either straight, rounded, or concave. (3) The *spirillum,* which is spiral.

3. *The most important surgical microorganisms,* are: Staphylococcus pyogenes aureus, staphylococcus pyogenes albus, staphylococcus pyogenes citreus, staphylococcus cereus aureus, staphylococcus cereus albus, staphylococcus cereus flavus; streptococcus pyogenes; micrococcus tetragenus, micrococcus pyogenes tenuis; gonococcus; pneumococcus; bacillus pyocyaneus, bacillus typhosus, bacillus tuberculosis; streptococcus of erysipelas; bacillus of tetanus; bacillus of anthrax; bacillus coli communis; and spirocheta pallida.

4. *The bacteria liable to be mistaken for the tubercle bacillus,* are: the bacillus of leprosy, the bacillus of the smegma, and Lustgarten's bacillus. "The differential diagnosis between these four organisms depends upon the following reactions: When stained by the carbol-fuchsin method, commonly employed in staining the tubercle bacillus, the Lustgarten's bacillus becomes almost instantly decolorized by treatment with mineral acids, particularly sulphuric acid; whereas the smegma bacillus resists such treatment for a much longer time, and the lepra and tubercle bacillus for a still longer time. On the other hand, if decolorization is practised with alcohol instead of acids, the smegma bacillus is the first to lose color. The bacillus tuberculosis and the bacillus of leprosy are both very retentive of their color, even after treatment with acids and alcohol. If, then, we treat the preparation, stained with carbol-fuchsin, with sulphuric acid, Lustgarten's bacillus becomes almost at once decolorized. If it is not immediately decolorized, heat with alcohol; if it is then decolorized, it is the smegma bacillus. If it is still not decolorized, it is either the leprosy or the tubercle bacillus." (From Park's *Pathogenic Bacteria.*)

5. *Ptomains* are basic, nitrogenous organic substances produced from protein material by the bacteria which cause putrefaction. "Owing to the wide variations in the chemical constitution of the ptomains, they possess no characters by which they can be distinguished as a class. Some are strongly alkaline and basic, others only feebly so. Some are liquid, oily and volatile, others fixed and crystalline. Some are very prone to oxidation, and are active reducing agents, others are quite stable. For the same reason, no analytical method is possible by which vegetable alkaloids and ptomains can be separated from each other *en masse,* nor are any reactions known to which all ptomains respond while vegetable alkaloids do not, or the reverse." (Witthaus' *Manual of Chemistry.*)

Three sources of ptomain poisoning: Canned meats, ice-cream, and decomposing fish.

6. Widal's test in typhoid fever "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. * * * A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology.*)

8. (*a*) *Phagocytosis* is the faculty of certain cells (notably the mononuclear and polynuclear leucocytes) to take up and destroy bacteria.

(*b*) *Chemotaxis* is the property by virtue of which certain living cells approach *(positive chemotaxis)* or move away from *(negative chemotaxis)* certain other cells or substances.

(*c*) *Opsonin* is that quality of a serum which makes a microorganism more susceptible to phagocytosis.

9. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbol-fuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it

thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

10. (*a*) *Aërobic* is a term which denotes that a microorganism requires the presence of oxygen as an essential to its growth.

(*b*) *Anaërobic* is a term which denotes that a microorganism requires the absence of oxygen as an essential to its growth.

(*c*) *Diplococci* are cocci (see Answer 2 above) associated in pairs.

PATHOLOGY.

1. *The pathological changes that take place in the blood in malarial fever,* are: The red cells are destroyed, and therefore reduced in number; the red cells lose their coloring matter; the serum is colored with hemoglobin; granular pigment appears in the blood; the plasmodium malariæ may be found in the blood; the white cells may be diminished; the total quantity of the blood is diminished; the specific gravity of the blood decreases.

9. *Three varieties of external hernia:* Inguinal, femoral, and umbilical.

Usual contents of the sac in oblique inguinal hernia: Intestine and omentum.

PRACTICE OF MEDICINE.

1. Topographical occurrence of edema. A. *General edema:* (1) Beginning at the feet and extending upwards—cardiac weakness or disease. (2) Beginning in the face and extending downwards—renal disease. (3) Beri-beri, multiple peripheral neuritis, trichinosis, and lymphedema.

B. *Edema of upper half of body:* (1) In early stage of renal dropsy. (2) Of arms, head, and neck, in thoracic aneurysm, large double hydrothorax, and mediastinal tumor. (3) Edema of one arm, in enlarged lymphatic glands and tumors, and thrombosis of axillary vein.

C. *Edema of lower half of body:* (1) In early stage of cardiac dropsy. (2) Hepatic cirrhosis. (3) Abdominal tumors, enlarged liver, spleen, pancreas, or mesenteric glands. (4) Chronic malarial poisoning, anemias, cachexiæ, wasting diseases, long continued slight hemorrhages, thrombosis of femoral vein, lymphedema.

D. *Circumscribed, and usually single swellings:* (1) Over precordial space, in purulent pericarditis. (2) Over affected side, in empyema. (3) Over mastoid process, in mastoiditis. (4) Over parotid gland, in mumps or parotid suppuration. (5) In right hypochondrium, in hepatic abscess. (6) Over posterior lumbar region, in perinephritic abscess.

E. *Circumscribed multiple swellings:* In angioneurotic edema, purpuric edema, and giant urticaria. (Condensed from Butler's *Diagnostics of Internal Medicine.*)

2. Cardiac arrhythmia has no particular clinical significance, unless it accompanies some disease. According to Butler *(Diagnostics of Internal Medicine)*, search should be made for one or more of the following: (1) Valvular cardiac disease, especially mitral lesions, in which it is usually, but not always, a sign of beginning failure of compensation, passing in many instances into delirium cordis; simple dilatation, chronic myocarditis, sclerosis of the coronary arteries, and fatty degeneration; possibly obscure changes in the cardiac ganglia, and overstrain or impaired nutrition in wasting diseases or long-continued fevers. (2) Poisons circulating in the blood, such as alcohol, coffee, tea, tobacco, digitalis, aconite, and belladonna, or the toxines of the infectious diseases, especially of typhoid fever and pneumonia. (3) Diseases of the intracranial contents, meningitis, hemorrhage, abscess, softening, concussion, and not infrequently mental excitement. (4) Neurasthenic conditions resulting from excesses or overstrain. Brief attacks of moderate arrhythmia are not uncommon in neurotic individuals, following even a slight departure from their usual habits in food, drink, or exertion. (5) Digestive disturbances, acute or chronic, and jaundice or constipation, particularly if associated with an unusually hypochondriacal frame of mind. (6) More rarely arthritis deformans, exophthalmic goiter, and renal disease.

5.

ACUTE PNEUMONIA.	EXUDATIVE PLEURISY.
Onset very sudden and symptoms severe—convulsions, etc., cough first, followed by pain in the side.	Onset moderately sudden, and symptoms not severe—chilliness and pain in the side, followed by cough.
Temperature very high, 104° or often 105° F.	Temperature not high, 101.5° or 102° F.
Pulse - respiration ratio greatly disturbed.	Pulse-respiration ratio not disturbed.
Bright crimson flush on the cheeks, and the muscular prostration is considerable.	Face is pale, and there is little loss of muscular power.
Cough is short and hacking or in paroxysms; and the sputum, when brought up is rusty and tenacious.	Cough is dry and painful, and patient tries to repress it.
Organs not displaced.	Organs displaced.
Dullness on percussion not complete, and the sense of resistance almost nil.	Dulness complete, with sense of great resistance
Respiratory sounds tubular, and fine crepitation heard at border of consolidation.	Respiratory sounds much diminished, and friction heard at upper margin of effusion.
Vocal resonance increased.	Vocal resonance greatly diminished.
Vocal fremitus increased.	Vocal fremitus diminished or absent.
The physical signs are limited to the front or back of the chest.	The physical signs are found both at the back and front of the affected side.

7.

ACUTE MILIARY TUBERCULOSIS.	ENTERIC FEVER.
Temperature curve is irregular.	Temperature curve is characteristic.
Diarrhea is not common.	Diarrhea is common.
Roseolar eruption not common.	Roseolar eruption is generally present.
Widal reaction is negative.	Widal reaction is usually positive.
No typhoid bacilli in blood, urine or feces.	Typhoid bacilli in blood, urine, and feces.
Tubercles may be found in the choroid.	No tubercles in the choroid.
Pulse and respiration are usually much more rapid.	Pulse and respiration rapid.
Epistaxis is rare.	Epistaxis is common.

OBSTETRICS.

2. At full term the *placenta* is a soft, spongy mass, roughly saucer-shaped, from six to nine inches in diameter, about three-quarters of an inch in thickness at the central point, and weighs about one pound. Its *functions* are: (1) To supply nourishment to the fetus; (2) to act as a respiratory organ for the fetus; (3) to act as an excretory organ for the fetus.

4. The *most reliable signs of pregnancy*, are: (1) Hearing the fetal heart sounds; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) hearing the umbilical or funic souffle.

6. *Causes of vomiting in pregnancy*, are: (1) Reflex disturbance, due to rapid growth and excessive distention of the uterus; (2) disease or displacement of uterus, tubes and ovaries; (3) disease of pelvis or gastrointestinal tract; (4) excessive sexual intercourse; (5) renal disease or disturbance.

GYNECOLOGY.

2. *Kraurosis vulvæ* is a progressive atrophic shrinking of the tissues of the vulva.

5. *Caruncle of the urethra* is a small, red, fleshy growth, situated generally on the posterior part of the meatus of the urethra.

6.

TUBERCULOUS CYSTITIS.	GONORRHEAL CYSTITIS.
1. Located chiefly about the trigone.	1. Not at all so confined.
2. Inflammatory reaction zone absent.	2. Clear inflammatory reaction zone, later changing to dull brown color
3. Local tuberculous cystitis not very common; general tuberculous cystitis very rare.	3. Of common occurrence both local and general.

TUBERCULOUS CYSTITIS.	GONORRHEAL CYSTITIS.
4. Characterized by presence of small tubercles situated about the trigone and ureteral orifices.	4. Characterized early by insular areas of reactive inflammation, with healthy or nearly healthy intermediate mucosa. Later insular areas becomes confluent and extend over whole mucosa.
5. No projecting tufts of pus.	5. Projecting tufts of gonorrheal pus are apt to be present. In chronic stage regions of elevation may be excavated by ulceration.
6. No subperitoneal extravasation of blood.	6. In very acute stage there is subperitoneal extravasation of blood.
7. Bacillus tuberculosis.	7. Gonococcus.
8. Often extension from kidney and from general tuberculosis.	8. Extension from vulva, vagina, or urethra.
9. History of tuberculosis. Great pain; hematuria.	9. History of gonorrhea. Less pain; seldom blood in urine.

—(Dudley's *Gynecology.*)

HYGIENE.

2. The *alimentory principles of food*, are:

I. Inorganic { Water. / Salts.

II. Organic { Nitrogenous—Proteids. / Non-Nitrogenous. { Carbohydrates. / Fats.

The *function* (and constituents) are shown in the following table, adapted from Notter and Firth's *Hygiene:*

FOOD.	FUNCTIONS.
Proteids.	
1. All substances containing nitrogen, of a composition identical with, or nearly that of albumin; proportion of N to C being nearly as 2 to 7.	Formation and repair of tissues and fluids of the body. Regulation of the absorption and utilization of oxygen. May also form fat and carbohydrate, and yield energy sometimes. In most foods the above, both animal and vegetable, are largely converted into albumoses and peptones during digestion.
2. Substances containing a larger proportion of N are apparently less nutritious; proportion of N to C about 2 to 5½.	These perform the above functions less perfectly, or only under particular circumstances.
3. Extractive matters, such as are contained in the juice of the flesh.	These substances appear essentially as regulators of digestion and assimilation, especially with reference to the gelatin group.
Carbohydrates.	
Substances containing no N, but made up of C, H and O; the O being exactly sufficient to convert all the H into H_2O.	Production of energy and animal heat by oxidation. Form fats and possibly some proteids.
Fats.	
Substances containing no N, but made up of C, H and O; the proportion of O being *less* than sufficient to convert all the H into H_2O.	Supply of fatty tissues, nutrition of nervous system; supply of energy, and animal heat by oxidation.
Salts.	Support of bony skeleton, supply of HCl for digestion, regulation of energy and nutrition.

The *objects of cooking*, are: (1) To destroy parasites, and so avoid danger of infection; (2) to break up the starch grains, and so allow the digestive juices to come in contact with the granulose; (3) to loosen the fibers of the meats, and so render them more accessible to the digestive juices; also to convert the insoluble collagen into soluble gelatin; (4) to make the food more palatable, more desirable and more digestible.

9. *Ptomains* are basic compounds containing nitrogen, and produced from proteid material by the bacteria which cause putrefaction. They are *found* in decaying animal tissues and fluids.

The *chief poisonous ptomains* are: Tyrotoxicon, mytilotoxin, cholin, neurin, neuridin, putrescin, cadaverin, gadinin, muscarin, tetanin, typhotoxin.

The *general symptoms of ptomain poisoning* are: Onset in less than twenty-four hours after the ingestion of the noxious "food," chilliness, vertigo, headache, thrist, abdominal pains, nausea, vomiting, diarrhea, cyanosis, weak and rapid pulse, cutaneous eruption sometimes, subnormal temperature at times, convulsions.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	July 5

THE EYE OF YESTERDAY AND OF TO-DAY.*

BY FRANCIS VALK, M.D.,

NEW YORK.

I APPRECIATE fully the honor of appearing before this Society to-night, and while I am aware of my own shortcomings in an address that may prove interesting, yet I could not refuse the kind invitation of your genial chairman. But, having accepted that invitation, the question was at once presented to me in this way. What shall my title be, or what subject can be of sufficient interest to repay you for your presence and your attention? Now, your president has kindly allowed me to select any subject pertaining to the eye, and it has occurred to me that a partial history of the eye of yesterday and of the eye to-day may prove of sufficient interest. With that thought in mind I trust you may find some food for reflection and for instruction, while on my part I am sure your free discussion must be of much benefit to myself. As I understand, this Society is composed chiefly of members of our honored profession who have taken as their life's work that of the general physician, the greatest part of all specialties of medicine. If I am correct, I may well ask the question: What shall the general physician know of the diseases and abnormal conditions of the eye and the ocular apparatus? Now, to present a paper on the strictly scientific side of the question is not my object to-night, but just to touch upon the eye as it was presented to his classes by one of the most eminent men of America many years ago, and then to discuss the many advances that have been made in the past three decades, during which I have had the pleasure and the profit of my work in the diseases and in the abnormal conditions of this most important organ of pleasure and of special sense. Now, for a few moments let me take your thoughts to a time one hundred and thirteen years ago. At that time the celebrated Benjamin Rush was the professor of physiology at Philadelphia. Listening to his teachings there was a young man, evidently very bright and an excellent penman, and while listening to these lectures, this young man took them down in his notebook in longhand. (They had no stenography and typewriters in those days.) Those notes he then copied in a well-bound book with many flourishes, headlines, and an index, the whole comprising two volumes (which I have treasured in my library). Now, surely by such testimony as this we may know the thoughts of the eminent lecturer not only on general medicine, but on the eye, in which we are chiefly interested to-night, and as we seek this information, what do we find? You will pardon me if I quote to you a few sentences from these remarkable lectures. The first on the "Sense of Seeing," the second on "Vision," and the third on the "Pleasures of the Eye." In the first we have, "Light I believe to be matter . . . it is invisible in the night because it is in a quiescent state." "Light analyzed in a prism discovers seven colors." On "vision" we have "Rays coming from different points of an object are by the humors and cornea refracted to a point on the retina." It is so to-day, but you will note he makes no mention of the lens. Lastly we have "the Pleasure of the Eye," in which he describes the pleasure of the mind as we appreciate "light, color, figures, motion, sights, distance, and magnitude all combined to pour an ocean of pleasure on this sense." Then we are told that the "Queen of Sheba died from the sudden pleasure of seeing the buildings of Solomon," and the lecturer also relates his own pleasure of seeing a balloon on fire in the sky. And finally, as he combines the pleasure of the eye and the ear he says: "Lewis, fifteenth king of France, used to mix a bed of roses and a band of music with his venereal pleasure," but adds "these combinations have arisen from ignorance of the laws of sensation." Such is the physiology of the eye more than one hundred years ago, and what shall we say of to-day? How shall we present to you the vast advance that has been made in ophthalmology since my entrance into this honored profession, now three decades ago? To-day our knowledge of the diseases of the eye in all its etiology, its diagnosis, and its treatment is remarkable, and ophthalmology has become a true science, one that is so large that it has been well said "we now have specialists in a specialty."

Now, in the time at my disposal let me briefly review some of the most notable advances that have proven of immense advantage to the human race and that have prevented so many cases of what might have been permanent blindness or, at best, diminished vision. I shall be able to cite only a few of these, but most notable of all I find the advance that has been made in the prevention and in the treatment of that most dreaded disease, ophthalmia neonatorum. You are all familiar with the characteristics of this disease of early childhood with its copious secretion, its gonococcus, its tendency to extend to the cornea and its rapid threatening of the integrity of the sight. You have all met these cases with the large white leucoma covering the cornea after recovery, the perforation of the eyeball, the cornea, iris, and lens so massed together as to destroy any possibility of a restoration of the vision by any operative treatment. These cases were often presented to us at our clinics in the dispensaries and in the hospitals, and how hopeless the surgeon's art would seem as the eyes of the little one were opened and it was discovered that the destructive process

*Read at a meeting of the Ulster County (N. Y.) Medical Society, Kingston, N. Y., December 1, 1908.

had finished its work. But to-day I am happy to say that, thanks to the excellent method of prevention instituted by Credé and our knowledge of the necessary care and treatment of these cases, it is now seldom that we are called upon to tell the anxious mother that nothing can be done to restore her child's eyes. Now, you are all aware of this method of prevention by which the dropping into the child's eyes a solution of silver, ten grains to the ounce, will effectually destroy the bacteria and render this disease innocuous. And furthermore, if this disease, through neglect or inattention, should be established, do we not know that the daily instillation of the solution of silver and the constant attention to cleanliness will in nearly all cases, if the cornea is not involved, result in a complete cure? In this connection allow me to suggest to you, as a remedy of prevention or of cure, a solution of nitrate of silver that I have used in my practice with a result that to me has been exceedingly useful and effective. It is well known that the usual solution of nitrate of silver tends to deteriorate by the deposit of an oxide of silver, in this way making that solution of silver much less effective and more unreliable to combat this disease. But some years ago I noticed a formula advising the addition of the sweet spirit of niter to the solution, by which we prevent the precipation of the oxide from the free nitrous acid in the solution of niter; hence we have a solution of pure nascent nitrate of silver, in which state it is well known to be much more effective. My formula, as used for the past fifteen years, has been five grains of nitrate of silver, two drams of sweet spirit of niter, and six drams of water. This makes a clear solution and may be freely applied to the delicate structure of the cornea and the conjunctival sac without the slightest fear of injury to these structures. Now, in the treatment of all cases of gonorrheal ophthalmia in the adult and of ophthalmia neonatorum, it seems to me that the most important points to remember are cleanliness, asepsis, and gentleness. I have seen the eyes very seriously endangered, if not lost, by too great an effort to dislodge all secretion from the conjunctival sac. The corneal epithelium is exceedingly delicate, and the slightest injury to this membrane may be the point of rapid introduction of the disease germs to the corneal tissue, which will rapidly lead to destruction of the eye. In the acute stage when the lids are swollen and hard, we cannot evert them or even force a pipette between them. Now, they must be kept clean by washing every two hours with a solution of boracic acid or a solution of peroxide of hydrogen. If necessary, the lids may be gently raised with the retractor so that we may be informed as to condition of the cornea. If the lids can be everted, I apply daily with a small cotton swab the solution of nitrate of silver as suggested. Atropine is not necessary in these cases, unless the cornea is involved.

Aside from the conjunctival disease we may have an implication of the eye from the systemic infection following an acute attack of gonorrhea. Bull reports five cases that were followed by very severe attacks of iridochoroiditis, with pain, swelling of the lids and chemosis, discolored iris, and reduced vision. Leber claims that these microscopic germs must find their way into the circulation and by those paths enter the tissues of the eye. De Wecker claims that all cases of iridochoroiditis associated with an inflammation of the joints are always due to gonorrheal infection.

These systemic complications, fortunately, are very rare. But the local condition or disease is not infrequent, and unless carefully watched, will leave a dense white opacity in the cornea with adhesions of the iris to its posterior surface. At a symposium on this subject I closed my remarks with these words: "A disease so serious in its acute stage, so fatal to sight in its consequences, so serious in the reduction of the earning power of the individual, and yet so easily prevented, is well worthy of our serious consideration."

In connection with the advancement that has been made by the use of the Credé method of prevention, I may mention a condition of paresis of the accommodation in children following an attack of diphtheria. Some years ago I frequently noticed these cases in my clinical work in which I would see children of seven or ten years of age unable to read, and with some diminished vision at the distance. This had occurred suddenly and in taking the history it was usual to find that the child had had an attack of diphtheria. While this condition tends to recovery, it is to be noted that these cases are very seldom presented at the clinic to-day. Now, we find that from investigations by R. Bylsena of Middleburg, Germany, of all children who have been treated with the serum, not a single case has shown this postdiphtheritic paralysis of the accommodation. I think this is a notable advancement in medicine and one that should be more fully noted and confirmed by the general practitioner. May we not consider these two conditions as remarkable advancements in the practice of ophthalmology to-day, and in which the credit is wholly due to the advancement of general medicine?

To-day, the diseases of the interior of the eye are as an open book to the ophthalmologist by the use of the ophthalmoscope, and though this instrument is truly one of precision, yet its use should be more common in the hands of the general physician. By its use we can note the condition of the blood-vessels, both the arteries and the veins, as well as the general background of the eyeball. In this limited space do we not see the changes produced by many systemic conditions, in many cases before they are noted by their general symptoms? Can we not see the changes produced by an arteriosclerosis when we note the depression in the veins as the hardened arteries pass over these vessels almost closing their lumen? How often do we notice the changes in the vessels and retina in disease of the kidneys, which produce the characteristic appearance of albuminuric retinitis by which we can confirm the diagnosis and warn our patients of their danger. It is also by the use of the ophthalmoscope that we see the conditions indicating diabetes, syphilis, anemia, and the various pathological changes due to disease of the retina itself. All these conditions were many years ago classed as amblyopia or amaurosis—general terms which simply indicated loss of vision, but to-day their true character and significance are well known. We turn the examination with the ophthalmoscope to the disc or optic nerve entrance, and here we may find the evidences of the "choked disc," that frequent forerunner of some neoplasm or disease of the brain, or we note its peculiar color, we may suspect a rectrobulbar neuritis, a disease so common among those who worship too freqnently at the "flowing bowl."

All these conditions can be readily seen by the physician who will perfect himself in the use of this valuable instrument. To see the normal conditions

of the retina is not difficult, nor does it require a special amount of practice; and if one appreciates the normal conditions of the eye ground as shown by the ophthalmoscope, he can readily note all abnormal or pathological conditions. Some years ago I had the pleasure of reading a paper before our State Society on the use of the ophthalmoscope, and concluded as follows: "We do not contend that the general practitioner must of necessity become an expert in the use of the ophthalmoscope, but we believe that he must depend upon its revelations, if he would early recognize certain disorders of the brain, arterial degeneration, and renal complications."

Now, in the treatment of the diseases of the eye to-day I have little to say, as I think the medical armamentarium of the oculist is small indeed. But a few general thoughts may be of interest as to diagnosis and treatment. At the last meeting of the Academy of Ophthalmology, held in Cleveland last August, a very interesting discussion took place in reference to the subject of how much knowledge of ophthalmology the general physician should have, or, in other words, how much the undergraduate shall be taught in our colleges. This question is difficult to answer and is one that needs an answer from the physician in constant general work. It seems to me that in the larger cities, when the services of an oculist can be so readily obtained, the general practitioner should burden himself very little with the diseases of the eye and the various phenomena pertaining thereto, as the subject is too large to understand it all, and we may well say, where shall we draw the line in his studies of the subject? But on the other hand, the country physician, from the isolated nature of his practice, must inform himself of all the knowledge possible of the care and treatment of the eyes. To this end I shall endeavor to point out some general objective symptoms by which the cases may be treated so as to prevent serious complications or the result of serious impairment of the vision. As I have conducted my clinical work at the Post-Graduate Hospital, it has seemed to me, that from the appearance of a patient, as he is seated before me, and before asking any question, we may at once conclude what is the probable cause of his present disease of the eyes. You may say, that is a "snap diagnosis," and you would be correct; yet in many cases it will be confirmed in the examination, and I am not speaking for the benefit of those well versed in the practice of ophthalmology.

Now, let us consider the more common diseases of the eye, that is to say, those of the cornea and iris and those of the conjunctiva. What of our "snap diagnosis" in these cases? May we not just notice if we have a condition of photophobia or dread of light? And if so, what does it indicate? If our patients do not present this symptom, we may consider it doubtful if we have any disease of the deeper or most important parts of the eye; in other words, a case that does not seem to suffer from this dread of light, probably has some affection of the conjunctiva which, if proved by examination, may be treated with the usual astringents, but if they do shade and close the eyes, then our diagnosis is more serious and atropine is indicated. Now, this simple rule will cover many cases and, if followed, will prevent much serious injury to the sight. Let me illustrate this. A case of conjunctival disease may not cause any serious injury, but if we have an inflammation of the cornea or iris, which always is accompanied by photophobia, then the use of atropine will prevent an opacity of the cornea, if that substance is involved, or an adhesion of the iris, if an inflammation of that delicate membrane is present. I have many times seen an iritis treated as a simple conjunctival disease until the iris was completely adherent to the capsule of the lens, when a few drops of atropine in the early stages of the disease would have prevented these adhesions. This simple rule will prevent many complications until a more full and complete diagnosis can be made and the proper treatment instituted. A little child is brought to us with the head pressed against the mother's shoulder, the eyes tightly closed, but no evidence of any secretion. In such a case we may at once conclude, that the little one has an inflammation of the cornea—a keratitis, and on opening the eyes we find the infiltration of the cornea, as we see the more or less localized whiteness of the membrane with the "rosy zone" of congestion or redness around the cornea. These cases are very common, and proper attention to the diet and the use of atropine will rapidly cure them.

I shall not attempt to review the advance in the surgery of the eye to-day. It has made the same rapid strides as the treatment, and seldom do we see the cases of eye diseases and eye operations shut up in dark rooms devoid of light and air in the fear of some unknown danger. To-day our eye wards are well lighted and ventilated, and the tendency to take off the bandage is more or less prevalent. To-day the progress is much more promising and the percentage of failures is much less in all our operative cases. The prognosis in cataract is now very promising, and I feel confident in saying that our percentage of failures in the operations for senile cataract, either simple or combined, has fallen from 8 or 10 per cent to almost, if not fully, one per cent. Such excellent work is due to a more complete technique and antisepsis in the operations and after-care of our cases.

In this connection, the drug cocaine has played a very important part, and our patients with senile cataract need not fear the operation, as under this beneficent drug the procedure is perfectly painless and we avoid the unpleasant aftereffects of an anesthetic. Glaucoma—that dread disease with its increased tension, its slowly decreasing field of vision, and the final result in complete and incurable blindness, may now be controlled by eserine or pilocarpine, or, these failing, then a well-performed iridectomy will seldom fail to arrest the progress of the disease and may improve the failing sight. Ocular surgery has also advanced in the domain of ocular motility, and the little one whose eyes are crossed need no longer suffer the teasing of its companions, as at the proper time a careful operation will place the abnormally turning eye back to its proper position. I think it is now conceded that all cases of squint are due to some defect in the rotation of the eye, in other words, that we have a want of development in one of the lateral moving muscles, always showing as a deficiency in the rotational power, and to-day I think that our first consideration should be to increase this by a suitable operation. For some years I have followed out this rule with uniform success, always doing the shortening operation on the weak externi, in convergent squint, and then, if necessary, a guarded tenotomy under cocaine, until the position of the optic axes is correct. By this method every case is finally successful; in many we have binocular vision, and an over-correction by this method is very rare.

To-day the advances that have been made in the examination of the refraction have been very great and perhaps the day will come when my prophecy made two years ago will prove true. At that time I stated that the day would come when we, as physicians, would be able to fit glasses without questioning our patients; or, in plainer words, I trust that we may so perfect our objective tests of the refraction that we may know what correction will be required. Perhaps I was too optimistic, but to-day we can tell if a myope's refraction is benign or is pernicious, that is to say, that it will remain stationary or that it will increase with all the possible dangers of a posterior sclerochorioiditis, detachment of the retina, floating bodies, and diminished vision. All this may be known if we will study the radius of the cornea. Benign myopia is well shown in the shortened radius of curvature, if we accept 7.65 mm. as the normal curve; while progressive myopia will always show the flat cornea or one with a much longer radius. Hypermetropia, that condition of refraction which in children causes them to be dull, nervous, and backward in their studies, is readily corrected by glasses, while astigmatism, a word so common to-day on the lips of the laity, is readily diagnosed and measured by the retinoscope and the ophthalmometer. The normal eye may not need glasses until old age brings presbyopia, but an abnormal condition of refraction must bring distress unless corrected if our people will continue to use the eyes for constant reading. We see too many children wearing glasses in all our large cities but we cannot turn these children out to play in the fields; the streets of the city are no place for them; they must turn to their books for amusement, and if they have an error of refraction they must use the glasses or suffer from the symptoms of eyestrain. It is true that many reflex symptoms are of functional origin and that they have their commencement in an eyestrain from an error of refraction. This should call for the services of the physician and not those of the optician, as the latter cannot fully complete the work in many cases. To my mind one of the most important advances in modern ophthalmology to-day has been the results of the investigations in the motility of the eyes, that is to say, the ability to move the eyes in their automatic and in their volitional function. To-day we find that the movements of the eyes seem to be controlled by two distinct and separate functions, first the power to fuse the images on the two retina; this is binocular vision. This function is purely automatic, controlled by a special centre in the floor of the third ventricle, and is in no way under the control of the will. Now, secondly, we have the movements of the eyes, fully under the power of the will, controlled by centres in the higher brain or cortex, which enable us to move the eyes, by conjugate motion, to any and all parts of the field of space. It seems to me reasonable, though denied by many, that an end-organ so delicately poised on the contents of the orbits, so beautifully moved and controlled by the action of twelve muscles, so perfectly turning in unison with each other, must cause certain reflex symptoms and distress if this delicate muscular action should be abnormal in any way. Hence, the study of heterophoria, or ocular imbalance, will well repay the student of ocular rotations and these investigations in orthophoria, dextrophoria, anophoria, esophoria, and exophoria will be extremely interesting as they may be the prime cause of many reflex symptoms, of which I may mention, headpain, nervousness, pain in the back of the neck, and even, as claimed by some, chorea and epilepsy. I am somewhat in doubt in reference to these claims in the last two conditions, but I have noted many cases of chorea and of migraine very much relieved by the proper adjustment of an evident imbalance of the ocular muscles. In the treatment of these cases we may have success by the use of glasses and prisms; but some will not tolerate these and we must look to operative eye surgery for the correction of these cases of heterophoria, in which I prefer the shortening operation on the weak muscles as the best and the safest procedure.

One of the most complex problems of the present day, associated with the advancements of ophthalmology, one that has caused much controversy in the profession and that is many times denied by some, is the symptom complex, generally called eyestrain. If we listen to the arguments of many of my confrères in the domain of ophthalmology, we would conclude that eyestrain is the prime and essential cause of "all the ills that flesh is heir to," and that the simple process of examination for, and selection of, a pair of glasses may and will relieve all cases of epilepsy, chorea, migraine, and many other obscure conditions; but when we read these reports, how much shall we place on the facts and how much on the enthusiasm of the writers?

Now, I cannot endorse any of these, which seem to me, extravagant propositions. Recently we had a paper by a very prominent oculist in which the argument is elaborately advanced that even the symptom complex of Ménère's disease of the semicircular canals is due to an error of refraction, and that the correction of this with glasses will stop the dizzy sensations, the vomiting, and the tinnitus. Gould's argument is very elaborate and almost convincing,* but I cannot accept the theory of any such close connection between the eye and the ear. We do know that some cases will suffer certain symptoms similar to those of Ménière's disease, as dizziness, which may be promptly relieved by the use of suitable glasses, but that this procedure should have any connection with the tinnitus and deafness is almost too "far a cry" to satisfy my own experience. A simple hyperopia will frequently assert itself as the age of presbyopia comes on, and dizzy sensations are frequently the most pronounced symptom.

I have not seen the case that had the other symptoms associated with it, nor have I seen a case of Ménière's disease cured by glasses. On the other hand, if we listen to the arguments of the neurologists, we must conclude that eyestrain has no relation to any of the so-called reflexes, be they functional or organic; and to claim that eyestrain may be an occupational neurosis seems to cause a very decided obsession in my friend Patrick of Chicago, as he says the use of the eyes is merely a normal function and is physiological. But Patrick says we may abuse some of our functions and then we must "pay the penalty," even if the use of the eyes is a normal physiological function. Yet we can abuse this function by overuse and then we must "pay the penalty" which means that we must suffer from eyestrain. But may we not accept a much broader view, be more conservative in our opinions and try to understand the subject in its true light? It seems to me that the general consensus of opinion by the profession may be summed up in this way, that eyestrain does exist and that it does cause certain symp-

*Gould: Medical Record, Oct., 1908.

toms that are functional. But, even if functional, they do cause much distress and suffering, and these symptoms are relieved by the correction of this strain on the organs of vision. If we accept these propositions, then we may well ask: What are the causes of eyestrain, what are its symptoms, and what are the means of relief in the armamentarium of the physician? Granting then that we do have such a complex condition as eyestrain, we may well ask the question: Why is this eyestrain so prevalent at the present time? Now, we may say that our present civilization is the cause of so much eyestrain, if by civilization we mean the constant use of the eyes for near work. The demand for reading matter has increased a thousandfold during the past two decades, our country is dotted all over with the circulating libraries lending out books to "old men and maidens, young men and children," whereby they spend their time reading instead of indulging in that healthy relaxation and exercise that the general system needs. If we glance at the subject in this way, the etiology of eyestrain becomes very apparent, as it goes without argument that if the muscles which control our seeing function are constantly in action and we have an abnormal condition of the ocular apparatus, then nature must rebel and we have the phenomena of eyestrain as the result. The normal or emmetropic eye may stand an immense amount of physiological work, but too many fail to have this normal eye; nature has furnished them with what we as physicians consider an abnormal condition, and if so, these individuals must suffer, must "pay the penalty" if they attempt to use the eyes too freely.

Now, I shall not attempt to define the normal eye, but to discuss the question what are the causes of the abnormal condition? Primarily, we have the condition of the eye designated as an error of refraction, such as an hyperopia, a myopia or an astigmatism, due to an unequal refraction in the two principal meridians of the cornea; and secondarily, a want of balance, heterophoria, in the straight muscles of the eyes which will cause an inequality in the ocular motility.

I do not intend to burden this paper with special cases, but to illustrate my contention that eyestrain may be due to an error of refraction or to a want of motility in the ocular apparatus, that is to say, an imbalance, I will give you a few details of three cases in my private practice. Furthermore, I am willing to acknowledge that the vast majority of all cases of eyestrain are due simply to an existing error of refraction, yet certain cases also point to the fact that the symptoms may be due to a want of balance in the external ocular muscles without any objective or subjective evidence of a refractive error. The following cases will illustrate this condition:

Case 3953.—Mrs. A. L. B., age 25. Eyestrain. V. 20/15 each. Rejects all glasses. Refraction almost emmetropic: Latent convergent squint, 10°. All asthenopic symptoms relieved by prisms.

Case 4190.—Mr. D., age 25. Eyestrain, V 20/15. Refraction emmetropic, no astigmatism. Rejects all glasses. Latent convergent squint, esophoria. Prisms of no service; all asthenopic symptoms relieved by shortening the externus.

These are two very similar cases, in one of which we have perfect relief with the use of prisms worn constantly, and in the other we could not get relief until the muscular balance was restored by an operation.

Case 4744.—Mrs. M. W. N., age 25. Worn glasses without relief; eyestrain and asthenopia. V. 20/15, w + 1 D. cyl. ax 90°, each eye. Latent convergent squint or esophoria with dextrophoria. Complete correction of the astigmatism with glasses gives complete relief.

Here we present the relief of eyestrain by correction of the refraction alone.

These three cases illustrate very clearly the usual means or method of treatment of eyestrain, in which the final result cannot be predicted until these means are tried; as correction of the refraction may fail, prisms may be tried without benefit, and finally a suitable operation may be performed. Under this method of procedure, success will come in many cases, and our failures to relieve eyestrain will be very few.

It would be a long story to relate the many symptoms, as stated to us in the consultation room by our patients, and from which they seem to suffer more or less. I might say that many of these symptoms are heard in the stories of all patients; but it seems to me that some of them have a special reference to the ocular apparatus, and these must call for a special examination. Among the latter we find backwardness in children, inattention at school, rubbing, blinking, and pressing the lids, blurring of the vision, tilting or holding the head forward or backward, headpain caused by reading, writing, and sightseeing, vertigo and dizzy sensations, and headpain around, or back of the neck and around and in the eyes. All these symptoms evidently refer or point to some abnormal condition of the eyes, either refractive or muscular, and, unless there is some other obvious cause for the symptoms, call for a careful examination of the ocular conditions. This examination is imperative before we try to relieve certain symptoms with drugs that may be due to an abnormal condition of the eyes. Headache, that most common expression of the present day, has been referred to the eyes by the laity, but this is only a symptom that may be due to many other conditions; yet it is the one most commonly related in the office of the oculist. As a corollary to this paper I would refer the reader to a recent paper by Coggeshall and Maccoy* on this subject, in which they take the position that "eyestrain headache is due, not only to a refractive error, but may be due to a muscular imbalance;" and on the subject of migraine these writers state that an individual with migraine and having a decided neuropathic diathesis, will probably have an error of refraction or a muscular imbalance as the exciting cause of the phenomena of migraine. At the same time we must admit that other conditions of autointoxication may be the underlying cause of the pain.

It goes without argument that the diagnosis of eyestrain must be along certain lines that necessarily require certain special training. It is also, without doubt, a part of the work of a physician, a part of his armamentarium for the relief from the ills that flesh is heir to; and if the demands of a so-called civilization require more use of the eyes than in the good old days we like to talk about, then these demands must result in certain symptoms, be they functional or not, which come within the practice of medicine as much as the mechanical fittings of a truss or a brace for an orthopedic deformity. An optician may be qualified to fit certain refractive cases and may do it perfectly, but he is not qualified to do all the work that is required for the correction

*Journ. Am. Med. Assoc., January 4, 1908.

of all cases of eyestrain; while the law requires and demands that all conditions of the eyes that may arise do come within the domain of the practice of medicine. I do not believe that the eye and its appendages are any different to-day from what they were fifty years ago; our population has increased a hundredfold, our opportunities to use the eyes at the near point have enormously increased, and our boys and girls are constantly using the eyes reading the many books and papers so freely and cheaply supplied. The result is that we must meet this condition by all the means at our command, when the anatomical condition of the individual requires our aid. The mere fitting of glasses is not the *sine qua non* of the treatment of eyestrain. Many other conditions must be taken into consideration, and indeed the intelligent practitioner will realize that the correction of a refractive error, or that of an imbalance of the eyes, may be of vast importance in the successful treatment of certain of his cases. Perhaps this statement might raise the question in our minds, should all physicians be oculists? By no means. If civilization has advanced in the past two or three decades, so has ophthalmology; so much so, that the subject has become too extensive for a physician to master all its details, as I have before remarked, even those of eyestrain, and yet be a good general practitioner. But while the physician in our larger cities may refer his cases, the country physician cannot readily do so, and he should be able to understand the subject of the refraction and the motility of the eyes. Let him know at least what may be considered as the standard of vision and motility of the eyes, as well as the normal sounds of the heart and the percussion note of normal lung tissue, and then, having recognized an abnormal condition of the eyes, he may or may not decide to correct it.

Is there a normal condition of the eyes? That question is too broad and scientific to answer in a paper of this scope, but we may make some suggestions in relation to it. To do so, I will not consider all the intricate methods of diagnosis used at the present day—we must leave these cases to the ophthalmologist, who is more or less proficient in the use of certain scientific instruments—but every physician can have a test card displayed in his office for the purpose of testing the visual acuity. Furthermore, he may have a candle placed at twenty feet in front of his patient, and with a small set of prisms or even the rod of Maddox, he can test the motility of the eyes. Now, with this simple outfit, and bearing in mind that we do have a standard of vision and of motility, he can readily decide the presence of an abnormal condition that may be the cause of an eyestrain and of its functional symptoms. Let me give that standard in a few words. Our standard vision is usually designated as 20/20, which implies that the eyes are adjusted for rays of light coming from infinity or twenty feet, and that the dioptric apparatus will focus these rays perfectly on the retina with the eye at rest. But our people are so familiar with the size and shape of the letters that I find we must raise this standard somewhat, and I think that 20/15 would be nearer the normal standard; that is to say, we should see letters at twenty feet whose secondary axial rays form a smaller angle than one of five minutes, or, to make this subject more simple, we can see letters at twenty feet that should be seen only at fifteen feet. To repeat, if each eye will see letters at twenty feet that are marked for fifteen feet, then we may say that the eye has normal vision. It is true that many eyes with abnormal refraction may have normal vision, but that subject comes within the domain of the specialist and not that of the general physician. Our object is to call the attention to, and to point out, the method of examination where the vision is below the normal, as, if the record only shows V. 20/40, then the sight is subnormal, and we may have some evidence of the cause of the eyestrain.

Having examined the visual power, we now proceed to test the motility of the eyes, or their power to fuse images, by the prism test. First, place a red glass before one eye, and as the patient looks at the candle, note if he has double vision and if so whether the images are crossed or homonymous; that is to say, is the red glass on the same side on which the red light is seen, or is it on the opposite side? If on the same side, it indicates a possible paresis or, at least, a weakness of one of the abductors or externi. If on the opposite side or crossed, it indicates a possible paresis or weakness of one of the adductors or interni. The Maddox rod is used in the same way and shows the same conditions. We follow this test by removing the red glass and placing a prism of six degrees over one eye with the base of the prism placed inwards. If this does not cause any diplopia, then remove that prism and place a prism of twenty degrees over the eye with the base outward. Again, if we have no diplopia, we may use stronger prisms in the same way. If, after finding the strongest prisms, base in and base out, with which the patient can fuse or blend the images of the candle at twenty feet, we then discover that the degrees of these prisms bear the relation of one of abduction to three or four of adduction, it is very doubtful if we have any muscular imbalance. Such is the simple, yet excellent test for the standard of the motility of the eyes. These are tests that should be in use in every physician's office, and the routine use of them in all cases that present any symptoms of eyestrain may assist in the diagnosis. To carry our examination beyond this point would come within the work of a specialist, who is more fully competent to work out the possible latent conditions, as astigmatism and certain muscular errors. These simple tests were the first ones that I was taught in my early work in ophthalmology, and, in my experience since that time, they hold as good to-day as three decades ago.

In presenting the above statements of the correct vision and motility, it must be understood that in some cases we may have eyestrain with the most perfect vision, and it has been suggested, as an axiom, that "the better the vision, the more the reflex troubles." While I doubt this, yet we do find that many slight errors of refraction are the prime cause of certain reflex symptoms. It is doubtful if any line of treatment will be successful, if these cases are due to a refractive error, or to a muscular imbalance. These people must submit to a careful scientific examination of the eyes for the correction of the existing abnormality by glasses or such other methods as may seem necessary. This examination is essential so that we may eliminate eyestrain as the cause of certain other reflex symptoms. But even accepting the proposition that eyestrain may be the cause of the symptoms, yet, with their accurately fitted glasses, even under a mydriatic, such persons will still feel the strain on the accommodation with pain about the eyes. If so, then we may find indicated certain general tonics, restricting the use of the eyes, outdoor exercise, and,

as a local application. I have found very useful a solution of eserine sulphate, 1/40 gr. to the ounce, one drop in each eye three times a day. This drug has a tendency to stimulate the ciliary muscle to action, and to lessen the strain on the accommodation in reading. The use of eserine as a ciliary tonic was suggested by the late Dr. C. R. Agnew at the time he was surgeon of the Manhattan Eye and Ear Hospital, and it has been of much service to me in many cases of eyestrain after the full correction of the refractive and the muscular errors. Furthermore, as regards any internal treatment in these cases of eyestrain that may be due to any muscular imbalance, Seguin, in 1892, published a very interesting article in the *New York Medical Journal* on eyestrain, particularly in reference to an original weakness of the nerves of adduction and abduction, in other words, any lateral muscular imbalance. In his final conclusions as to treatment in cases where the symptoms are increased by an act of accommodation and by convergence, or, we may say, where there is a tendency for the eyes to roll outward when at rest, exophoria, Seguin recommends the use of nux vomica or strychnine, and claims they are sometimes cured by a course of this drug. Furthermore, he says, if we find the fault in the power of abduction, or a tendency for the eyes to roll inward, esophoria, then the use of cannabis inrica, bromides, and atropine for the complete rest of the accommodation, is indicated.

I think this line of treatment will hold good at the present time. These are all cases of muscular imbalance, or as Roosa, the late president of the New York Post-Graduate Hospital, would call it, latent strabismus, and may be corrected by drugs, as Seguin suggests, by wearing prisms, or by an operation if needed. Change of scene and travel are useful, but should not be ordered until we have fully corrected all the visual defects. Again, after all these things have been done, we may find it necessary to allow the patients to use the eyes only by degrees, by the method called Dyer's plan—which I have found useful in some cases—in which we allow them to use the eyes only for stated periods a certain number of times a day.

We must all admit that eyestrain does exist in far greater numbers than in former years, that it is due to a civilization that demands much more constant use of the eyes, that many of our people must have certain abnormal development of the visual apparatus as regards the refraction and the motility, and that the general physician should have, or be aware of, some means by which he may realize the possible presence of eyestrain and then be able to take such means for its correction as may seem best.

I trust that I have not exceeded my time in this rapid and very incomplete record of my personal experience in this interesting field of ophthalmology during the past three decades. The study of all ocular conditions that present any pathological changes in the eye, with the estimation of all the complicated errors of refraction that we meet in our consultation hours, the exceedingly difficult questions to solve in many obscure cases of heterophoria, paresis, and paralysis of the ocular muscles, has been and always will be en exceedingly interesting study to myself. Hence I feel that some of you may have listened to the paper with interest and that I may have mentioned some fact or some condition that may be of much service to you. In a paper of this nature I have omitted many things. I have tried to replace the scientific side of my subject with the conditions that meet the oculist in his work of every day, and to give you my personal experience in as few words as possible, at the same time referring to those subjects that may be most interesting.

One more subject to touch upon, and my task is done. Every physician meets the conditions of double vision or diplopia in the course of his practice. What does it portray, where is the lesion, and what is the condition that is the cause? It seems to me that we can consider this subject in a simple, practical light. We know that the eyes are moved in the orbit by certain straight muscles, which, having their origin at the apex of the orbit and passing forward in their respective sheaths, partly encircle the eyeball to their insertions into the sclera, while the oblique muscles tend to keep the eye steady and essentially to keep the vertical meridians of the eyes parallel to each other. Now, an interesting physiological function of the eyes is that of binocular vision, controlled and governed by the unique fusion force, which enables us to see singly, at all times, though we have two eyes. Hence, if these straight muscles are normal in their development, their size, and their insertion into the eyeball, we must have single vision in all parts of the field of space. All this goes almost without saying, but when we consider all this and appreciate how delicately the eyeballs are poised (if I may use this word) in the orbital cavity, resting on a cushion of fat, their only attachments being the nerve behind and the tendons of the muscles surrounding, we can readily see how the slightest impairment of this beautiful mechanism can disturb the fusion force, and we have diplopia, or double vision. Now I wish distinctly to state that the double vision must be due to some pathological condition in the ocular apparatus when the look is in infinity; that is to say, a heterophoria, or weakness of one of the muscles, will not cause diplopia at infinity, though it may do so if we tend to destroy the fusion force by a cover over one eye, by a red glass, or when the eye is in the extreme parts of the field of rotation. But if we have the slightest disturbance of the nervous supply, a slight paresis of any one of the straight ocular muscles, then we must have diplopia, and the character of that diplopia will indicate which muscle is affected. Now, while the diplopia may indicate some pathological condition of some one or more of the twelve muscles of the eye, we must by some simple reasoning decide what muscles are affected, and perhaps where the lesion is situated. In the presence of diplopia it will be noted that one image, as seen by the patient, is not so distinct, is blurred; this must evidently belong to the deviating eye, and we must now make our diagnosis from the position of the false or blurred image. This we do by what is called the law of projection. Now, projection is a physiological function of the eye, by which the image of an object, as formed on the retina, is projected or seen in space and must follow certain laws which I will interpret in a few words. The location of an image in space always proceeds from an image on the opposite side of the retina, that is to say, an image seen outward comes from an impression on the inner side of the retina. Hence, when the image is seen outwards, we have homonymous diplopia, and crossed diplopia when the image is seen on the opposite side of the affected eye. Those are the two important rules, as nearly all pareses affect the

lateral moving muscles. Granting that, our diagnosis becomes simple, as homonymous diplopia must show that the image comes from the inner side of the retina, or that the eye is turned inward from weakness of the externi, and crossed diplopia must show that the image comes from the outer part of the retina or that the eye is turned outward from weakness of the interni. Following this rule and remembering that the indistinct image belongs to the deviating eye, the diagnosis of paresis of the ocular muscles is apparent. In paralysis of the ocular muscles the diagnosis is obvious, as the position of the almost immovable eye in certain directions at once indicates the muscle affected.

If there is one excuse that may be offered for the reading of this paper tonight, it is in the desire to bring before you some of the essential points that the general practitioner should know on the subject of opthalmology. He cannot know all the intricate means of diagnosis and of treatment, but I have endeavored to present the essential conditions as found in diseases of the eye and the ocular apparatus. If I have failed to illustrate the conditions fully to you, I must plead the want of time and trust that your discussions may correct these failures of mine. Ophthalmology as well as general medicine has made many and rapid advances in the past three decades, and yet we have much to learn and much to understand, as we study these complex end organs of the brain. To this end I trust I may always be a student of the eye of yesterday and to-day.

SOME SERIOUS LAPSES IN ADMINISTRATIVE HYGIENE.*

By HOMER WAKEFIELD, M.D.,

NEW YORK.

The aim of my paper this evening is to direct the attention of the profession to the prolific causation of disease involved in the pathogenesis of a group of factors which may be classified as decadent proteins, and including degenerate nucleins, degradation albumins, putrefactive products, and divers renegade tissue extractives when ingested as food.

It has long been a stigma on our fair country that, notwithstanding that we are now supplying a large portion of the world with food products which we produce in such prodigious quantities, owing to our lax hygienic laws we are ourselves probably the worst provided for of any civilized country: and, moreover, we pay more for wholesome foodstuffs at home than American products can be bought for abroad.

We expend millions of dollars annually for State and municipal departments of health which, owing to lax laws, avail us little in the protection of the people against this class of unwholesome and disease-breeding provisions. We are ignoring the causes of tuberculosis in cattle while fighting its transmission. We are forgetting the toxicity of retrograde metabolism and decomposition products, while we are too optimistic in our confidence in parasitic organisms as responsible for all our pathological woes.

We poison ourselves with decomposition and degradation nitrogenous products in milk, rank butter, bitter cream, musty eggs, decomposed poultry, etc., with perfect complacence in the knowledge that they have not been condemned from the bacteriological point of view. Our laws are thus exceedingly unequal and inconsistent. We overestimate our security from disease by inhibiting bacterial infection and growth on the one hand, and leave our fences down on the other. Pasteurization is not a panacea for retrograde metabolic and decomposition products any more than for dirt or dung contents.

The Hygiene of the Cow versus That of Milking and the Preservation and Delivery of Milk.—In the discussion of this subject I would not be construed as in any way deprecating the good work done, or the great strides really made by health authorities in this country. However, without underrating the importance of modern sanitation about the dairy, the storage and delivery of chilled milk, the maintenance of bacteriological and butterfat standards, as determined by skillful and careful daily inspection and certification, I would emphasize the fact that another factor is too often entirely neglected, namely, the hygiene and health of the milch cow.

This is the age *par excellence* of the recognition of the preventive factors of that class of affections formerly so prevalent and now so relatively scarce, namely, struma and scrofula, antecedent and predisposing to tuberculosis—especially sunlight, fresh, pure air, and adequate physiological exercise. New tenement laws, legislation against overcrowding, the opening of recreation piers and floating hospitals, cruising excursions of fresh-air funds, open air and school gymnasiums, etc., elegantly express the full present day recognition of good light, air, and exercise as factors of health in the human subject.

But how about the poor cow? Summer excursions to the dairy districts, especially to a few model dairy farms under the inspection of municipal health departments, present an exceedingly rosy picture of bovine conditions. The cows are driven in from the green pastures into ideal milking sheds, where they are cleansed and milked by white-garbed milkers, and the milk is then handled by sanitary methods and stored and delivered to the consumer in bottles which are sterilized and kept chilled.

If we inspect the average dairy in winter we have present in many respects a far different picture. The recognized requirements for light, air, and exercise of the human subject evidently are not believed to apply to the cow, for we find her housed in sheds with low ceilings. The recognized number of cubic feet of air per capita is deficient, the atmosphere is heavily laden with vile contaminations of decomposed urine and dung. The sheds are nearly dark in efforts at exclusion of exterior cold, the cow is so fixed by the neck bars that she can scarcely move out of her tracks, and she is not exercised out of doors often for weeks or more at a time.

According to Lane, "An investigation of fifty dairy herds in Pennsylvania by *Hoard's Dairyman* developed that 'about 75 per cent. of the barns were reported not sufficiently warm. This caused a waste of food nutrients. Not more than 10 per cent. of the stables were provided with any system of ventilation other than windows, holes in the floor over the stable, and hay chutes. In addition to pure air, sunshine was also lacking in most cases.'"

Apropos of my commentaries on food, Lane in his conclusions observes: "Too often the carbohydrates in the rations were far in excess of what the cow could utilize in milk production, and this resulted in waste. In some cases cornstalks were fed to the stock dry and uncut, only a part being eaten. Where protein crops were grown to supple-

*Read before the Medical Association of the Greater City of New York, January 18, 1909.

ment the pasture an increased milk yield and a greater profit were secured." And he might have added, a healthier cow resulted.

To cap the climax, the modern winter feeding has evolved from the bran and ground cereal feeds of the past to ensilage, an acid fermentation product of cornstalks; also brewing refuse, etc. As a consequence of this modern feed, the milk comes from the udder with an acid reaction. The ensilage of green maize (cornstalks), in common use in this country owing to its cheapness—also termed sour fodder—is characterized by La Far[5] as containing a relatively high percentage of volatile (fatty) acids. As compared to sweet fodder, or sweet ensilage, which is most popular in Great Britain and the continent of Europe, in which lactic acid predominates over butyric, acetic, and valeric acids, the sour ensilage exhibits a more mixed fermentation, with the acetic fermentation usually dominant. In sour ensilage the destruction of albuminoids is about 40 per cent., against from 13 to 31 per cent. of total nitrogenous matter in the sweet ensilage, thus greatly reducing the nutritive elements. The loss in carbohydrates is greater than in albuminoid elements.[5] According to La Far, "the ferments consume a large amount of the albuminoids initially present, and decompose them into amide compounds, ammonia derivatives, and even ammonia, all substances of but little, if any, use for the nutrition of animals which are to be killed as food." (p. 263.)

I believe it is customary for New York physicians to disregard the character of the feed of cows as related to the milk, and the difficulties of differentiating ensilage from bran and meal fed cows are admittedly insurmountable. I am aware of the fact, however, that in the smaller towns and villages the local physicians give preference to dairies feeding bran and meal over those feeding ensilage, when the milk is consumed by infants and invalids.

What is the effect of her winter's imprisonment upon the cow? I hold that it is exactly the same as we have learned by hard experience occurs in the human species, namely, primarily glandular disease, and, secondarily, tuberculous infection. The present market values of beef and milk bring home to us the effect of the wholesale destruction of cattle on the basis of the tuberculine test, and however unreliable that test, and the probability that bovine tuberculosis is innocuous to man, we must appreciate the existence of an unnecessarily large invasion of Winter housed milch cows by tuberculosis, a disease which is correspondingly uncommon in Western herded cattle.

The limitations of this paper preclude any discussion of the resulting pathology of the cow, other than to mention that we learn from veterinary works that the cow is subject to about the same variety of glandular diseases as the human subject, ranging from the acute to the chronic forms, thus providing suitable soil for the tuberculous and other parasitic infections, and hence for decadent hypalbuminosis, for toxins, degradation albumins in the blood, peptonuria, and albuminuria. That toxic proteins are imparted direct to human consumers of the milk of such cows, I believe is undoubted.

Scarlet fever, which is so much of a lymphatic disease that Hawley has proposed that it be designated as lymphatic fever, has an analogue in the Hendon disease of cows discovered by Klein in 1875.[4] Dr. E. F. Brush[1] of Mt. Vernon, N. Y., at the April meeting of this association last year, related instances occurring at Mt. Vernon, Ossining, and other places where scarlet fever was traced to the milk supply from herds affected with this disease. At Mt. Vernon sixty cases reported within eight days were traced to one herd so affected. And yet no more cases were reported when this herd was isolated. How exclusively glandular fever and measles depend on this source remains to the future to determine.

Johannessen's statistics, as cited by Forchheimer,[4] show the highest mortality for scarlet fever in Sweden and in Berlin to be in the coldest months of winter, when cows are most closely sheltered from the outer cold, while conversely all authors agree that in southern climates, where cows remain in the meadows the year round, scarlatina is rare or unknown. Statistics from medium climates are indecisive on this point.

That a toxic product exists in the blood of scarlet fever patients is proved by its excretion in the urine. This "scarlatinine," so called, has been proved poisonous by injection into lower animals,[2] and that it is a suboxidation product has been determined by artificially rendering it inert by oxidation. In previous monographs I have pointed out that all general suboxidations of sufficient degree are characterized by autointoxications and by glandular involvement.

Apropos of the above, it may be said that the so-called *Streptococcus scarlatinæ* of Klein is concerned simply with the septic element of severe cases, and, to speak plainly, it is nothing more than a case of infection of glandular suppuration by the ordinary *Streptococcus pyogenes*, and the same is the case in the Hendon disease in cows. That this disease extends to the milk is attested by the involvement of the teats and udder.

It is interesting here that the Department of Agriculture has been wrestling for some time with a disease prevalent in the Middle West, which is communicated to man through the medium of cows' milk, termed milk sickness, or trembles, the manifestations of which are said to resemble ptomain poisoning.[3] It is most typically characterized by nausea, vomiting, severe constipation, restlessness, muscular tremors, prostration, atypical pain, great thirst, and tendency to subnormal temperature

It has been variously attributed to eating corn fodder, white snakeroot, etc., the latter having recently been found negative. That the *materies morbi* is a product eliminated in the milk is proved by the appearance of the typical symptoms in the cow when milking is suspended for any reason, and the fact that the cow never exhibits it when milking is uninterrupted. Here appears another instance of retrograde metabolism and degradation albumins in the milk. Why do we so freely recognize milk protein toxins in the human subject from such a variety of causes and ignore them in the cow?

I do not hold that bad housing of cows during the cold months is the exclusive cause of the Hendon and other glandular diseases, for I recognize pronounced atmospheric humidity, wet and upturned soil, etc.—in fact the same general elements which we attribute as factors of etiology with the human subject.

No pathognomonic organism is as yet known in human scarlatina, yet I am not here to-night to discuss general parasitic pros and cons. Take the above for what it is worth

My object is to bring to your notice the obvious fact that milk plays the role of carrier of toxins as

well as infections, and thus point out a serious lapse in administrative hygienics in the neglect of this very important source of disease.

In this enlightened era of the recognition of degradation albumins, of toxic properties, toxic dissociation extractives, and general autointoxication and the general physiological and pathological chemistry of the proteids, milk should no longer be neglected from this standpoint.

It is interesting that our lawmakers have already taken cognizance of the baneful influence of the ordinary waste products in flesh foods by the enaction of laws against butchering animals for food until after any fatigue engendered in driving them to slaughter has been recuperated from and the products have been duly eliminated.

Former time practices of purposely fatiguing animals—in fact, torturing them to give the meat the "hazel nut" quality imparted by the metabolic products in excess, which we now get in beef teas and bouillon, and is so prized by connoisseurs—are now forbidden for the twofold purpose of preventing cruelty and preserving public health. These qualities are, however, provided by the flesh of the deer and hare, which are the victims of the chase, by livers, the cells of which envelop much of the waste products; the wild geese, especially during flight periods, and, lastly, cold-storage undrawn poultry, the flesh of which becomes impregnated with the decomposition products of the decadent viscera, decomposed fat, etc.; the latter, however, as we shall see shortly, is not a stable product, and when too long stored the flesh is as bitter as though impregnated with bile. As is well known, the normal human urine quite strongly exhibits the nutty odor of waste products.

The Pathogenesis of Undrawn Cold Storage Poultry.—A long suffering public has been imposed upon with many forms of "taxation without representation" since the establishment of American independence and such as our revolutionary forefathers never would have stood for. Among the many examples of imposing upon the public at an expense to the public far transcending the intrinsic value of the same is the now exclusive policy of weighing in to the consumer the undrawn entrails of poultry, in addition to the heads and legs complete—the so-called New York dressed, which has now become universal over our fair country for all manner of birds and poultry sold for food. While this custom is alleged to have been nationalized by the meat trust, and the market is thus cornered and monopolized in restraint of trade, since its establishment a few years ago, and it is still under control of these interests, it is also permitted by our lawmakers, in spite of the fact that the edible tissues absorb the toxins and decomposition products from the decadent entrails, and despite that laws are constantly enforced against the same or equivalent conditions in animals killed and sold for food, and notwithstanding that the poultry tissues are the more absorbent of the two.

Any school boy would comprehend the danger involved in attempting to preserve for any length of time an undrawn fowl without freezing, yet by the maintenance of a subfreezing temperature, when the day of reckoning does come and the poultry is thawed by the retailer, a much *worse* danger obtains from eating these birds. Slow mortification has long proceeded in the enteric viscera, as exhibited by the green discoloration, and many other evidences.

As the thawing extends from the surface inward the parenchyma is more widely expanded and loosened than before freezing, the surface tension is correspondingly lowered and free diffusion of the enteric toxins and decomposition products obtains, especially in those places unobstructed by bone, such as the thighs as they come into apposition with the bony openings of the carcass so affected. The thin abdominal wall contiguous to the inner aspect of the thighs appears to act as an osmotic membrane which enteric toxins appear to traverse, and serves as a collecting surface. Also fat degeneration in this location is quite pronounced.

Notwithstanding Miss Pennington's[8] report that putrefaction is not found before thawing, certainly, however skillfully thawed by the slow ice pack method, putrefactive products, indol, skatol, etc., are found in much of this cold storage poultry by the time it reaches the consumer. The parenchyma of the thighs thus becomes so impregnated with the bitter extractives and decadent products of the entrails as to make them unfit for ingestion, and even in varying degrees poisonous, ranging from a reducing action to albumose and possibly ptomain poisoning.

The well-fattened birds preserve the best exterior appearance. In fact, they are easily palmed off as fresh-killed, dry-picked specimens after a year in storage, and hence these are the types upon which the public is most gulled. Modern perfection in the methods of thawing the frozen poultry enables warehouse men to deliver from their storehouses the fattened types in external appearance like those fresh killed.

In these types, however, of well-nigh perfect appearing exterior, the meat on cooking is found much denser and dryer than when fresh; the subcutaneous fat, while present in situ and often expanded, is decomposed, and, besides being exceedingly bitter and ill smelling, is often acrid with dissociated fatty acids. It is also observed that the muscle sheaths and the intermuscular adipose tissue are most decomposed, the exceptional being the fat and the aponeurotic fibrous tissue interposing the abdominal wall and the inner aspect of the thighs.

Interposed between the abdominal wall and the thighs is to be found the greatest collection of decomposition detritus on the bird. It is of liver color, soft, gelatinous consistence, foul smelling, and of acrid bitter taste. The contiguous tissues exhibit a greenish tinge, and a taste and odor similar to the detritus.

The pathogenesis of these decomposition products may be divided into direct and ultimate. Of the symptoms of the former may be enumerated nausea, vomiting, anorexia, headache, drowsiness, and pyrexia; and of the latter, intestinal inflammation and intoxication, nephritis, and general subcatebolism.

The long overdue report on refrigerated undrawn poultry of the bureau of chemistry of the Department of Agriculture has finally appeared in the 1907 Year Book just issued, in an article by Mary E. Pennington,[8] of the bureau of chemistry. This report is such as any ordinary layman could have made, no less superficial. It is neither bacteriological nor chemical, but deals with the superficial aspects of poultry of one, two, and three years' storage, discoloration, odor, atrophy, softening, macroscopic changes of texture, etc. Upon the development of toxic albumoses she is silent.

The impression gained in reading the report is that an innocent type of enzymic autodigestion occurs which renders the tissues tender, easily torn, etc., instead of being a postmortem degeneration of serious import. She does close, however, with a suggestion that possibly some of the intestinal disorders and imperfect metabolism of dwellers of large cities may be due to this cause; nothing definite, however.

The Prime Evil of Cold Storage Egg Preservation.—The advent of great cold storage facilities which has in so many ways profited mankind has not been an unmixed blessing. And it is paradoxical that a product that has been most benefited by it is associated with one of the greatest abuses, namely, the egg.

It was a great thing when it became possible to preserve food products beyond the limited period of their availability, to be supplied to the consumer during the unproductive seasons. Now, however, as a result of the keeping qualities of refrigeration, we suffer by its use as a means of cornering the egg market and hoarding eggs at a time of year when eggs should all be fresh and cheap, and holding them at other seasons of the year at figures almost prohibitive to any but the wealthy, for general consumption, during the winter months.

A natural consequence of withholding from the market to the extent of maintaining high prices from one spring to another, owing to the restricted sale thus produced, a surplus is engendered at the end of the fiscal year, and these are then unloaded on the public as fresh eggs, while the really fresh ones are bought up from the producers and stored, to repeat the process for another year. The ultimate consumer thus largely uses stale eggs the year round or pays a substantial advance for the really fresh ones brought in by dairymen and others who take advantage of the high market to realize well for their products. I will omit the discussion of the chemical changes and pathogenesis of stale eggs, other than to say that they represent but another type of degeneration products and toxic degradation albumins, or albumoses.

As eggs and poultry of uncertain age, extending from one to three years in storage, are continually palmed off on the public as fresh, it is obvious that if laws were enacted obliging the dating of eggs as daily gathered and poultry as killed, with adequate penalties for fraud, and for offering either for sale, or selling either poultry or eggs after one year from date so marked, much good would be accomplished. Also punishment for the sale or offering for sale any products undated or imperfectly preserved for the period allowed. I am not so sure but what six months for poultry and nine months for eggs would be a practical, and certainly would be a more salutary, limit. The sale of poultry after one year of cold storage preservation should constitute a felony. All undrawn poultry and birds in market should be confiscated and destroyed.

In general, our departments of health fairly outdo themselves in bacteriological inspections of milk and other foodstuffs, and conversely they are correspondingly remiss in defending the consumer against the decadent and degradation protein products and their toxic derivatives. They occur in milk of pretuberculous cows, in refrigerated flesh food products, and in stale cold storage eggs. They are pathogenic directly as toxic albumoses, and secondarily as predisposing to infection, yet they are generally ignored.

Commercial avarice imposes them upon the public often under false representations and disguised appearances, and medical men and their families are duped as well as the most uninformed layman. Price paid is no guarantee of fresh poultry and eggs, of the health of a dairy herd, or the freedom of milk from toxic products.

ACUTE (HEMORRHAGIC) ENCEPHALITIS, WITH REPORT OF CASES.

By G. B. HASSIN, M.D.,

CHICAGO, ILL.

Besides the acute purulent inflammation of the brain substance known as purulent encephalitis, or brain abscess, there are at present recognized several forms of acute *non-purulent* inflammation of the brain substance known under the collective name of acute non-purulent encephalitis. Here belongs Wernicke's acute superior poliencephalitis, Strümpell's acute (anterior) poliencephalitis in children, or, which is more correct, acute infectious encephalitis in children, also known as Strümpell's paralysis, and, finally, the acute non-purulent encephalitis in adults, commonly described as acute hemorrhagic encephalitis. Then there also occurs non-purulent combined inflammation of the brain substance with that of the medulla and of the spinal cord which conditions are known as poliencephalitis superior and inferior, bulbomyelitis, poliencephalomyelitis, etc.

Wernicke described his form in 1881,[1] while the two other forms of non-purulent acute encephalitis were established as separate clinical entities by Strümpell in 1885 when he first described the disease in children,[2] and then again in 1890 when he observed it in adults.[3] Leichtenstern showed the probable connection of non-purulent encephalitis in adults with influenza,[4] and this encephalitis is therefore mentioned by some authors (as Oppenheim, for instance) as Strümpell-Leichtenstern's form. Before Strümpell's publication on this subject, there was described under encephalitis cases not only of inflammation, but also of softening of the brain substance (red softening, yellow softening) whatever the cause thereof might be.[5]

The clinical picture of either form of encephalitis, as well as the anatomy and pathology, is quite characteristic, so that a diagnosis usually does not

offer any particular difficulties, especially in Wernicke's form where the external ophthalmoplegia is pathognomonic, and in Strümpell's infantile paralysis where hemiplegia sets in after an acute febrile course. The only form that often presents very great difficulties in the diagnosis is the third form, the acute hemorrhagic encephalitis, which either remains unrecognized altogether or passes under some other diagnosis, as meningitis, typhoid fever, intestinal toxemia, hysteria, etc.

Meningitis is the disease for which acute hemorragic encephalitis is commonly taken, both having sometimes the same clinical picture, and even the same etiology. The other reason for confusion of these two morbid conditions is that the authors of text books on nervous diseases devote too much space to discussion of different forms of meningitis and speak very little or nothing at all of non-purulent hemorrhagic encephalitis. Therefore, physicians coming across the latter do not even suspect its existence.

As an illustration how difficult it is sometimes to differentiate between encephalitis and meningitis, I will briefly cite a case which I saw seven years ago in Nothnagel's clinic in Vienna and in which such an experienced physician as Nothnagel himself was utterly helpless in making a correct diagnosis.

The patient was a boy, fifteen years of age. He was brought in the lecture room in a comatose condition. The eyes and the head were drawn toward the right and the left half of the body was paralyzed. About two weeks previously he had undergone a surgical operation, an osteotomy for genu valgum. He felt well after the operation for three days, *i.e.* there were no complications on the part of the wound, but on the fourth day he began vomiting. On the eighth day a left-sided hemiplegia developed with epileptiform twitchings in the paralyzed side, and the patient fell in a comatose condition in which he was brought to the lecture room. The examination showed some rigidity of the neck, no edema of the papillae, and lumbar puncture was negative; it gave a clear transparent fluid which did not coagulate.

Nothnagel could exclude fatty embolism, tumor, and abscess of the brain, and made a probable diagnosis of tuberculous meningitis with cerebral edema.

The boy died the same day, and the post mortem performed by Weichselbaum on the following day confirmed the existence of edema of the brain, but the cerebral membranes were found perfectly normal, and no tuberculous meningitis was found. Neither was an abscess nor a tumor found, but the thymus was large, and Nothnagel ascribed to this enlarged thymus the cause of death with all mentioned symptoms. "Formerly," said Nothnagel, "when I was a student one frequently spoke of asthma thymicum, a peculiar dyspnea in children, who succumbed to this morbid state. Death was supposed to result from compression of the trachea by the lobes of the enlarged thymus, but Friedleben proved that death in such cases is due not to pressure, but to some disorder in the central nervous system. The expression 'asthma thymicum' was introduced by Arnold Paltauf of Vienna. The anatomical substratum of this disease is a hyperplasia of the lobes of the thymus; hypertrophy of the tonsils, as was the case in our patient; hypertrophy of the retrobronchial and tracheal glands, of the glands at the base of the tongue; hyperplasia of the spleen, etc. Such patients are of a lymphatic constitution, anemic, and easily fall sick after some physical or psychical trauma, chloroform narcosis, etc. Cases of sudden death have been ascribed to chloroform narcosis, when the patient really suffered from status thymicus. Death usually occurs within eighteen to twenty-four hours from the beginning of the disease. That Friedleben's theory is correct, that the central nervous system is really affected in this condition, being the chief factor, has been also proven by our case, by the edema of the brain, which was also noted in the four cases observed in Rudolf Spital of this city. Thus, the main symptoms in this case were as follows: Three days after the operation the patient was feeling well; after eight days of vomiting paralysis set in with convulsions followed by coma and death. All this speaks for status thymicus, which is a very rare disease."

This elaborate discussion by Nothnagel of a thymic state by which he wanted to explain a case of acute encephalitis was entirely upset by Weichselbaum, who found from further studies of this case that the cause of the clinical symptoms and death was not status thymicus, but influenza. Weichselbaum made cultures from the brain tissue and found pure cultures of Pfeiffer's influenza bacilli. The patient had had grip some time before the operation, and the lesion of the brain substance that followed soon after the operation was an encephalitis as the result of influenza.

Nothnagel did not give an elaborate report of the anatomical and pathological findings in this case, but I distinctly remember that there was no mention made of any hemorrhages which usually are found in similar cases. These hemorrhages may be capillary, *i.e.* very small, or large enough to destroy entire portions of brain tissue. They occupy the gray as well as the white matter, and may be scattered all over the central nervous system, not only in the brain tissue, but also in the medulla, spinal cord, and cerebellum. Usually they affect the large central ganglia, as can be seen from Schmidt's case, which was dissected by Weigert and more minutely studied by Edinger.[6] The nucleus caudatus was reduced by hemorrhage to mere fragments, the lenticular body was covered with fissures filled with blood, and the same lesions could be seen in the internal capsule, and numerous capillary hemorrhages were also found in the internal capsule and in the putamen and lenticular body. Bloody fissures and capillary hemorrhagic foci were also found in the right central ganglia where the internal capsule and the entire lenticular body were transformed into a bloody mass, and a small hemorrhage had also taken place between putamen and external capsule. Microscopically there were to be found hyperemia of the vessels of the cortical and subcortical regions, proliferation of the neuroglia tissue, vessels with unchanged walls, dilatation of perivascular lymphatic spaces surrounded by corpora amylacea (Brooks),[7] while Dana and Schlapp found epithelioid cells around the distended capillaries and round-cell infiltration around the vessels.[8] The nerve fibers were found broken up, the pyramidal fibers degenerated, and the nerve cells themselves were in a state of chromatolysis; sometimes the nerve cells are entirely destroyed, as well as the nerve fibers. The cerebral membranes were sometimes found congested, especially when the cortex was much involved. In such cases the name "meningoencephalitis" is justified.

The anatomical lesions just described are to be met with only in severe cases of acute hemorrhagic encephalitis, but there undoubtedly also occur cases with less destructive lesions in the brain, capable of complete or partial restitution, in which the clinical course is accordingly less pronounced. Here must be included the following case which I observed about eight years ago in Russia.

The patient was a young man twenty-three years of age without any bad antecedents. He took sick with fever, pain in the limbs, and headache, which symptoms his physician diagnosed as due to influenza. The patient recovered in a few days, when he was suddenly frightened by a dog. The next day he began to vomit, complaining of headache and fever. When I saw him, about six days later, he had a left hemiparesis with involvement of the left facialis and a pronounced sensory aphasia. He forgot the names of things shown him, did not understand questions which remained unanswered, and, though he could talk, his speech was unintelligible. The temperature at the time of my visit was normal, the pupils were unequal, but reacted to light and accommodation; Kernig's sign was absent, and there was no rigidity or pain in the neck and back. Sensibility was not impaired, tendon reflexes were normal, while the skin reflexes were diminished on both sides. There was retention of urine and feces.

The sensory aphasia, combined with the hemiparesis, and the history of an infectious disease, were sufficient to justify the diagnosis of encephalitis. The patient was in a stationary condition for about two weeks more, when I left the city permanently, and I therefore cannot tell what was the outcome in this case. Judging from Oppenheim's cases,[9] some of which much resembled this one, the prognosis in such cases is not bad: after weeks and even months of illness the encephalitis passes away leaving no traces at all or some more or less serious defects in the central nervous system.

Besides the aphasia which was here the most striking and pronounced symptom, the probable etiological moment, the fright, is of interest, this fright playing, in my opinion, an important rôle in the etiology of encephalitis. This can be seen from the history of the following case:

Doctor D. S., fifty-one years of age, married, suffered from emphysema and chronic bronchitis for the last eight years. During the last six years he twice had bronchopneumonia and in the winter (December) of 1906 had the grip which passed away in about seven days. In March, 1907, the doctor again took sick with bronchitis and fever from which he recovered in a few days. On May 6, 1907, he was taken with fever, headache, cough, and severe acute bronchitis, recovering in about nine days. During the following four days he was out of bed, but felt extremely weak, though complaining of nothing else. He was up, enjoying outdoor life in his garden, and intended to go to his office in a few days. On the seventh day after his apparent recovery he accidentally noticed in the evening edema of the feet, which so frightened him that he at once took to bed with a temperature of 104°. He did not sleep the whole night, was delirious, trying to get out of bed, and was in the same condition the next day. He complained of severe headache in the occipital region, was perfectly rational, and refused to take the thermometer because "it made him nervous." There was no vomiting, no stiffness of the neck, the bowels moved after an injection, the urine was voided normally. The lungs, heart, and throat were normal. He had some appetite and ate a slight meal. In the evening of the same day he had profuse sweating, chills, and headache, but no vomiting. The night was very restless. The bowels moved from calomel. The next day, May 24, vomiting set in, the temperature was 103°, the headache was terrific, but otherwise the condition was the same till about 3 P.M., when he vomited twice, and became quite exhausted after this, staring vacantly at the walls. At night he showed drowsiness and slight twitchings in the right leg, did not answer questions, though he talked a little and asked for water. In the morning of the third day of the disease he again had profuse sweating (the clothes had to be changed), severe headache, constipation, and retention of urine. The urine was drawn through a catheter and showed absence of albumin. He could walk, supported, to another bedroom, complaining of a terrible headache, and after lying down, he began to twitch with the lower jaw, as if he had a chill. He understood everything, but it was hard for him to talk. About 1 P.M. he became very restless, the look was staring, questions remained unanswered, he hardly could be kept in bed and was not quiet even for a minute, constantly trying to get up. He remained in this condition the whole day and the following night, the temperature keeping at 103°, no vomiting, but constipation and retention of urine. Stiffness of the neck was noticed by a physician during my absence, but I did not see it. Kernig's sign was absent, the pulse was regular, full, not above 90. The restless condition with the above symptoms continued the whole next day, May 26, so that examination was impossible. The left arm and leg became rather stiff, ptosis of the left eye appeared in the evening, also involuntary passages from the bladder and intestines, and complete left-sided paralysis. Death occurred on the next day with the symptoms of edema of the lungs.

To recapitulate briefly: a man fifty-one years of age, without any antecedents as syphilis or alcoholism, a sufferer from chronic bronchitis and emphysema, falls ill with influenza from which he recovers in about nine days and, when ready to follow his usual occupations, is suddenly frightened on seeing his feet swollen. At once he has chills, sweats, and headache accompanied by high temperature. These symptoms increase in intensity during the next three days, followed by extreme restlessness, complete aphasia, left-sided hemiplegia, coma, and death. In this case four days elapsed between the influenza and beginning of the nervous symptoms. The majority of authors show that some time must elapse between the recovery from influenza and the beginning of encephalitis. This interval may be days, weeks, and even months. Then the age is given as young, between fifteen and thirty, while in this case the patient was fifty-one years of age, and Dana's patient was even older, sixty-seven years. Oppenheim says that the female sex is chiefly predisposed to encephalitis, but all my cases were in males.

In the fourth case the patient was a boy eleven years of age. He was perfectly well till July 4, 1907, when he was picking strawberries the whole day in the woods. In the evening of the same day he developed a high fever, but did not complain of any headache. He remained in this condition for

about three days, when I was asked to see him. The temperature was then 105°, pulse 108 of good quality. The throat, ears, heart, lungs, and abdomen were normal. Respiration also was normal, about 24. The pupils were of equal size, normally reacted to light and accommodation, reflexes, cutaneous and cremaster, were lost, while the tendon reflexes were normal. What struck me in this case was the absolute indifference of the patient to my examination, even to that of the throat; questions remained unanswered; the patient would not obey instructions, would not show his tongue or open his mouth, and was absolutely indifferent to the surroundings. When any part of the body was irritated, he would remove it mechanically or rather in reflex manner, just as in experiments with frogs whose hemispheres have been removed. There was no expression of suffering in the boy's face; he was lying quietly, looking indifferently at some subject in the room, paying no attention whatever to the people about him.

I diagnosed acute encephalitis on the ground of the complete aphasia, as there were no other signs or symptoms of brain lesion. While examining the patient I could notice slight twitchings in his right leg and lips, and, before I left the place, clonic convulsions appeared in the right leg. This new sign of focal lesion in the cortex, together with the aphasia and the peculiar apathy of the patient, confirmed my diagnosis, and, taking into consideration the rapid course of the disease and the course in the previous case, I made an absolutely unfavorable prognosis. The boy died the next day.

The histories of these cases, short as they are, contain all the clinical facts a physician can find at the bedside, on which few facts he must build his diagnosis, and, what is equally important in these cases, the prognosis. The laboratory methods are here of little benefit, because the blood does not give any particular signs in favor of encephalitis; the examination of the eye fundus sometimes gives the picture of edema of the papilla, sometimes the ophthalmoscopic examination is entirely negative, and lumbar puncture, which is of such a great aid in diagnosis of meningitis, is here of no avail. In the first case reported here lumbar puncture was negative, so was it in the hands of other observers, and Oppenheim[10] even warns against performing the same in acute hemorrhagic encephalitis in view of the tendency in this disease to hemorrhages. Therefore, we must base our diagnosis of acute encephalitis chiefly on clinical facts, and these usually are very scanty. It is a great temptation to make a diagnosis of typhoid fever, as it was diagnosed or suspected in the last case of mine, or of intestinal toxemia, as in the case No. 3, or meningitis, as in the first case, with a corresponding favorable prognosis, which sometimes must be changed within a few hours. Therefore the presence of aphasia which never fails even in curable cases of non-purulent encephalitis and which appears earlier than the rest of cerebral symptoms, if looked for, will greatly help in making a timely and correct diagnosis. Hence follows, that in a case of doubtful acute symptoms accompanied by high fever, vomiting, headache, and severe restlessness, aphasic symptoms should be looked for, and a complete neurological examination carried out, or, at least, the diagnosis should be postponed for a day or two, and the prognosis should not be made at all. The difficulties in making at once a correct diagnosis of encephalitis are increased by the fact that the symptoms of this disease are not always alike, which is due to the fact that the pathological lesions are not always the same, as in each case different portions of the brain are affected.

There can be no doubt that the diagnosis of encephalitis was correct in all four of these cases. In the first case this was confirmed by post mortem, in the second case the sensory, or Wernicke's asphasia, and in the last two cases the asphasia with the subsequent paralysis leave no doubt that we had in all these four cases to deal with an inflammation of the brain substance itself. There were no etiological symptoms of meningitis, as in all cases the ears, heart, and eyes were normal; there was no history of traumatism, but in three out of the four cases there was a history of influenza, and in these three cases there was a free interval of apparent health between the time of influenza and that of encephalitis. That influenza is responsible for encephalitic lesions was first firmly established by a number of German clinicians as Leichtenstern,[4] Königsdorf,[11] Fürbringer,[12] Bückers,[13] Oppenheim,[9,10] and later on it was pointed out that any other infectious disease, even mumps[14] and gonorrhea,[15] and any intoxication, as poisoning with fish, meat, or sausage, are capable of producing encephalitis. But influenza is by far the more common etiological factor, so that acute hemorrhagic encephalitis is also known under the name of influenzal encephalitis. Sometimes there is no history of influenza, or any other infectious disease, and the encephalitis must then be looked upon as an independent infectious disease. This happened in my fourth case, and Oppenheim[17] thinks that a specific organism is the probable cause.

Thanks to Strümpell and Oppenheim acute nonpurulent encephalitis, at present, is rightly placed among recognized brain diseases and as such it is mentioned in all recent textbooks on nervous diseases, while in the textbooks of a few years ago (Gowers, Hirt, Dieulafoy) we look for it in vain.

Another point which I would like to emphasize is the rôle of fright as an etiological factor. In the first case there undoubtedly was a psychical factor in the etiology in the form of a surgical operation. The boy had not long since recovered from influenza when he had to undergo a surgical operation on the knee joint, and the nervous excitement connected with the operation undoubtedly affected his central nervous system, and together with the previous infectious disease, influenza, was instrumental in producing encephalitis. The same factor figures in the second case, where a dog badly frightened the patient who a few days before had an attack of grip; and in the third case, the cerebral symptoms developed when the doctor, recovering from his grip and intending to resume his practice, was badly frightened by edema of the feet and at once developed a set of symptoms which were misunderstood for a relapse of the grip. This moment, fright, is mentioned by B. Sachs[16] in the history of a case, and by Oppenheim.[9] The latter says: "It is hard to decide what was the cause of the encephalitis—the influenza which the patient had a few weeks before or the psychical excitement which he experienced before he took sick; or, probably, both these moments must be taken into consideration." The last point to which I wish to call attention is absence of uniformity of symptoms Rigidity of the neck was absent in all my cases, though it is mentioned in the first case, and in the

third case this was observed by another doctor for a short time, but even if the rigidity was present, it was not so marked as in meningitis, and was not found by the majority of authors. The genito-urinary organs show incontinence in the period of coma, otherwise there may be retention, as in cases 2 and 3; the reflexes are sometimes absent, sometimes exaggerated. In short, the neurological examination gives such misleading results, that time is absolutely necessary to get more facts for an exact diagnosis. Of course, twitchings or convulsions in the limbs are a good and reliable sign, but they appear comparatively late. Therefore, I must again point out the diagnostic significance of *aphasia*, which, in combination with the peculiar *restlessness* and following apathy, indicates a serious lesion of the brain substance which, upon careful examination, will prove to be acute encephalitis.

SOME FACTORS IN THE ETIOLOGY OF A COMMON COLD.*

BY ROBERT CURTIS BROWN, A.B., M.D.,

MILWAUKEE, WIS.

A COLD in the head is an affection which probably dates from the time when man first began to use artificial means to protect himself from the elements. The word catarrh, which the ancient writers applied to a cold in the head, is derived from the Greek word Καταρρεω which means to flow down. This word catarrh perpetuates the earliest idea of the etiology of a cold, for, in the time of Galen and Hippocrates, it was supposed that the secretions of the nose flowed from the brain and were in the nature of a cerebral purge. The old view of the cerebral origin of nasal catarrh has left evidences in our modern nomenclature and in various expressions and beliefs of to-day. The pituitary body gets its name from the supposed origin of the discharge in that gland. The French call a cold in the head a *rhume de cerveau*, a cold in the brain. Various sternutatives, hellebore, for instance, are supposed to clear the understanding. The cerebral origin of a cold in the head was believed in until the end of the seventeenth century when Schneider of Wittenburg proved conclusively that the nasal mucous membrane was the source of the catarrh. In honor of Prof. Schneider, we call the lining membrane of the nose, the Schneiderian membrane.

An acute rhinitis, or what is commonly known as a cold in the head, is an acute inflammation of the Schneiderian membrane. A catarrhal inflammation (which is the character of the inflammation of a mucous membrane such as the Schneiderian) is a reaction of nature like any other inflammation, and its exudation depends upon the nature of the tissue. Catarrhal exudation in general consists of abundant mucin, cast off mucous cells, and leucocytes. The number of leucocytes determines whether the inflammation is purulent or nonpurulent. The catarrhal inflammation of the nasal mucous membrane differs from other catarrhal inflammations in the large amount of serum discharged. It has been determined that this serum comes from the membrane covering the turbinate bodies. As there are few serous glands in this tissue, it was supposed that the serum was an exudation from the turbinate vessels, but modern physiologists are agreed that it is a true secretion in which the epithelial cells have a vital part, taking the watery constituents from the blood and depositing them, modified, upon the surface of the mucous membrane. The turbinate bodies become very much congested with blood, the tissue becomes infiltrated with water, and there is a condition of stasis. The swelling of the mucous membrane and the turbinate bodies occludes the nasal passages and interferes with proper drainage and breathing. Passing briefly over the symptoms I will remark that they have a definite sequence depending upon the pathological condition. The first stage is a congestion, followed by the secretion of watery serum, which becomes more mucous as the mucous glands become involved and finally mucopurulent as more leucocytes leave the blood vessels to become part of the discharge. Various symptoms result from lack of drainage and the occlusion of the passages. The inflammation may extend to the contiguous sinuses and passages, but this tendency to extension is not characteristic of earlier attacks and is seen mostly in those who take cold easily and often. As the habit of taking cold becomes more frequent, we find the usual process of extension often reversed and the cold, commencing as a laryngitis or pharyngitis, extending upwards, ends in a rhinitis. But, if there is primarily an inflammation other than a rhinitis, there is always a history of some antecedent inflammation of the nasal mucous membrane.

It is not my purpose to discuss all the causes of coryza. There are a large number of predisposing causes, such as a deviated septum or adenoids,

*Read before the Milwaukee Medical Society November 10, 1908.

which lead to mechanical obstruction. There may be a low grade of inflammation ready to be exacerbated by a fresh attack. Faulty conditions of hygiene may render one especially susceptible to colds. Acrid vapors, when they are inhaled, and also certain drugs when they are eliminated by the nasal mucous membrane, will cause a coryza. It is a concomitant of many infectious diseases, but it is then probably due to the irritation caused by the elimination of the specific poison of the disease and not due to the infecting microbe.

The prevailing opinion among physicians is that a common cold is an infection. There are two theories: One, that the cause is specific; the other, that, the resistance of the body having been lowered by exposure to cold, infection is accomplished by one or more of the innumerable microbes that either normally inhabit the nasal cavity or accidentally happen to be present. On the theory that the cause of a common cold is specific, many observers have isolated from the nasal discharge different microbes and ascribed the cause of the cold to them; but, as yet, no one has been able to cause the symptoms of acute rhinitis from either the pure culture or the discharge of the nose. If the common cold is a specific infection, it is certainly a mild one, having none of the systemic symptoms of an ordinary infection. Knowing what we do of immunity, it seems rather improbable that the nasal mucous membrane should not long ago have become immune to such a mild specific infection. Probably the majority of physicians will incline to the lowered resistance theory. This, however, on investigation, seems more improbable than the other. Exposure to cold for a considerable time will, undoubtedly, lower the resistance of the body but, as we will note further on, a common cold is not acquired from long exposure to great cold, but under entirely different circumstances where there is no evidence of a lowered resistance of the body. One of the main functions of the nose is to filter the inspired air and free it from the germs it contains, so that when it reaches the lungs it is sterile. From long association with pathogenic germs, the resistance power of the nasal mucous membrane has become enormous. It does not seem conceivable that exposure to a slight draft which has no apparent effect on the rest of the body could so lower the resistance power of the nasal mucous membrane as to permit infection from the germs already present. There are so-called colds which are of an infectious nature, but they should be dignified by the name of influenzas. They have prodromic symptoms, and systemic symptoms, and all the earmarks of infection. Dr. Davis of Chicago has shown that the Pfeiffer bacillus is not the sole cause of influenza. There are many other microbes which cause symptoms similar to influenza and which may very likely enter through the nose, although the throat and tonsils are probably quite as often the point of entry. The severe types of colds that appear as epidemics are probably of microbic origin. The nose is by no means immune to infection. According to Metchnikoff, the plague bacillus and that of leprosy, as well as those causing influenza, are among those that gain entrance here, and we have many examples of its infection with the various pus germs, the gonococcus, and diphtheria bacillus.

Many authors, assuming that a common cold was not due to infection but to some vasomotor change consequent to exposure, have advanced various theories to explain its etiology. Rosenthal believes that the chilling of the surface of the body contracts the peripheral capillaries and drives the blood to the internal organs, thereby causing their congestion. Seit advanced the hypothesis that the vasomotor centers having been excited by sensations from a chilled skin, impulses were sent to particular organs, which, being points of least resistance, became congested, and in many persons certain channels seemed to be especially open to the reflected stimuli. Bosworth believes that the function of heat production enters into the question. He thinks that, if this process is stopped in one part of the body by a sudden chill, it must be followed by increased activity in another part. In this way he accounts for the congestion which leads to a cold. Wakefield thinks that exposure to cold produces, in remote portions of the system, areas of suboxidation which become inflammatory foci. I will not discuss these theories severally nor show how, in my opinion, they fail to fulfil the conditions of actual experience or agree with our present knowledge of physiology. But, I might say briefly in answer to Rosenthal's theory, that, though exposure of the body to cold may be conducive to various morbid effects, it can easily be shown by everyday experience not to be the usual way in which a common cold is acquired. Bosworth's theory that heat production is decreased in one portion of the body and increased in another has no foundation in physiology. Wakefield's theory is the opposite of Bosworth's and also has no foundation in physiology. The hypothesis of Seit is probably the most nearly correct, and it is along the lines of his theory that I wish to make a further suggestion. It occurred to me while studying the subject that if a close relation between the functions of the skin and the nose could be established, a theory based upon that relation might be deduced which would agree with our common experience and would also be physiologically sound. The nose has a respiratory function of vast importance. In normal breathing, all the inspired air passes through the nasal cavity. In the nose the air is filtered, warmed, and saturated with moisture, no matter what the external surroundings or atmospheric conditions. That the mucous membrane of the mouth and pharynx is inadequate to furnish the amount of moisture necessary to protect the delicate epithelium of the bronchi and lungs, is shown by the rapidity with which the mouth and throat become dry when mouth breathing is attempted. Physiologists tell us that about 5,000 grains of water (one pint) are added to the expired air in twenty-four hours. It has been proved by experiment that the greater part of this water comes from the nose. There is no mucous membrane of equal area where so much water could be secreted. The mucous membrane of the rest of the respiratory apparatus secretes only mucus, but in the nose we have a special apparatus for the secretion of water. It is the erectile tissue of the turbinate bodies. There are few serous glands in the mucous membrane of the nasal region. The function of secreting serum is undertaken by the cells overlying the turbinate bodies. Unless the blood vessels underlying the membrane were very large and numerous, they would be inadequate to supply this large demand. Nature has, however, furnished this region with tortuous vessels of very large calibre. In addition to supplying the inspired air with moisture, the turbinate bodies have the function of warming the air.

No matter what the temperature of the inspired air, the expired air is warmed to five-ninths the difference between the temperature of the body and the outside temperature. Physiologists have determined that the sole source of heat is in the nose. When cold air is breathed, a notable congestion of the turbinate bodies can be seen. This, on second thought, should impress one as quite remarkable when we consider that cold air, coming in contact with the end organs in the skin, causes the peripheral vessels to contract. In order to warm the inspired air and to evaporate the water secreted, a large amount of heat is required, therefore it is evident that the body must lose a large amount of heat by this means.

The main function of the skin is to regulate the temperature of the body. Whatever the surrounding temperature may be, the body temperature remains under normal conditions at 98 3-5°. The principal source of animal heat is from the individual cells of the body. There the metabolic activity takes place by which the more complex chemical compounds are reduced to simple ones, in the consummation of which process heat is generated. The amount of heat generated in the adult body is estimated to be about one degree for every half hour. In 36 hours the heat of the body would reach the boiling point if it were not continually being lost. The principal method the body uses to maintain a constant temperature is not by interfering with the production of heat, but by regulating the expenditure. Heat is lost through the skin by conduction and radiation, and by the evaporation of the perspiration. When it is necessary that the body should lose heat, the capillaries of the skin are dilated and more heat is lost by radiation and conduction. If that is not sufficient, the sweat glands are stimulated and perspiration is formed which, in evaporating, further facilitates the loss of heat. In order that no vasomotor centers may be accurately informed of the surrounding temperature, there are heat and cold points distributed over the surface of the body which, through the sensory nerves, keep the vasomotor center constantly informed of the changes in temperature to which the body is exposed. Thus the relation between the functions of the turbinate bodies and those of the skin is apparent. By both the body loses heat. The amount of heat lost, though varying considerably under different conditions, can be approximately estimated and the amounts compared. With the temperature at 60 and the atmosphere one-half saturated with moisture, the amount of heat lost by the body in warming the inspired air and saturating it with moisture would be about 300 calories in 24 hours. At the same time, taking a mean between the body at work and at rest, on a moderate diet, about 1800 calories would be lost through the skin, the proportion of heat lost by the nose and the skin being as one is to six. The skin and the nose are governed by the same vasomotor apparatus, a mechanism so delicately adjusted that it responds immediately, and usually accurately, to outside conditions. Is it remarkable that if one organ should fail in its function, the other should be affected? (It is interesting to note here that sternutatives or drugs which cause sneezing, contract the peripheral blood vessels. Indeed, Brunton says that they, by this means, raise the blood pressure, but I have been unable to find confirmation of that statement.)

Before the human race had become accustomed to clothes and overheated houses, colds were probably infrequent. Exposure to cold and catching cold are by no means synonymous. When the body is put to an effort to conserve its heat, as in exposure to cold, there is not much danger of catching cold, but when the body is put to an effort to lose its heat or is, in other words, overheated, there is great danger. It is when the body is at one time overprotected and at another underprotected, that there is the greatest likelihood of colds. When a skin area, which is usually overprotected, is exposed to a draft, an overimpulse is conveyed to the vasomotor center, an exaggerated response is sent out and the peripheral blood vessels are contracted over a large area. If, under these conditions, the temperature is taken, it will be found to have risen slightly. The body, which was attempting to lose heat, finds itself further embarrassed as the radiation from a considerable portion of the skin has been shut off. The turbinates being a means by which heat is lost, it is not strange that, under the circumstances, vasomotor impulses should be sent to them and that the tortuous blood vessels of the turbinated bodies should be dilated to the point of overcongestion. On this theory, both the so-called habit of taking cold and treatment for prevention of colds can be explained. The more often the nerve impulses are sent through certain channels, the easier does the impulse follow that channel, so that in a sensitive person the slightest exposure will result in a cold in the head. On the other hand, through the intelligent use of clothing, right living, and the proper use of baths, the skin may be kept in such a condition that it will send only normal impulses.

Even if we can evolve a plausible theory for the inception of a cold, there remains a still more difficult question to solve. If a common cold is, in its inception, a vasomotor congestion, caused by the exposure of sensitive skin areas, why does the process continue unnecessarily and run its usual course? If the congestion and increased secretion rendered the nasal mucous membrane more liable to infection, the mechanism would be easy to understand, for nature would naturally keep up the depurative process as long as the microbes were attempting to enter, or their toxins acted as an irritant, but the very conditions of congestion and increased secretion are admitted to be those under which infection ordinarily is least likely to occur. Although the nasal mucus is not bactericidal, yet Metchnikoff and others show conclusively that it rids the nose of a large number of germs in a purely mechanical way.

If we try to explain the process without infection, there is greater difficulty. The function of congestion and that of secretion are independent, each having separate afferent and efferent nerves. Congestion is regulated by two sets of nerves, vasoconstrictor and vasodilator. The blood vessels are normally kept in a state of contraction by the vasoconstrictors. The vasodilators must be inhibitory nerves as there are no muscles that can dilate a blood vessel. After the vasoconstrictor has relaxed the blood vessel as far as it can, the vessels can be still further dilated by the action of the vasodilators. Though congestion and secretion can take place independently as shown by the action of drugs and various reflex phenomena, yet they are mutually dependent in that the irritation of the organs of secretion is produced by congestion and, in order that secretion can take place for any length of time, an increased blood supply is needed. It is a well-known

fact that nature's reactions are often exaggerated and carried far beyond the point needed to accomplish the result intended. After the secretion is once started, the end organs of the secretory nerves having been stimulated by the primary congestion, a large amount of blood is necessary to provide the serum needed. It is quite possible that, under the severe demands made upon them, the tortuous blood vessels are dilated to a point where they lose their tonus. If the vasoconstrictor nerves in a dog are cut, the blood vessels dilate and remain so for about two weeks, when they gradually recover their tonus. During this time their musculature is still under the control of the peripheral end organs. The overdilatation probably explains the fact that, when a cold is well under way, drugs have little effect upon the congestion, though the turbinates can still be blanched by local applications. That the tonus of the vessels is lost is shown by the fact that, when emptied by gravity, they fill up quickly.

I am aware that some authors explain the continued reaction on the ground that it is inadequate to overcome the bacteria and toxins and that the reaction continues until sufficient antibodies are formed, yet at the same time they say that the conditions of the tissues are rendered more susceptible to infection. I do not think their reasoning is logical. Why is it that a cold may be aborted in the early stages, when surely there has been no time for antibodies to the infection to be formed, by means that are not directed against any infecting agent, but by measures and remedies tending to influence the hyperemia and secretion? Why is it that congestion and stasis render the mucous membrane more susceptible to infection when the Bier treatment is founded on those very conditions? I can readily understand how infection can take place in the contiguous sinuses or a passage like the Eustachian tube. Here the cavities are shut off by the hyperemia and, there being no drainage, pathogenic germs may flourish. It is quite possible that bad drainage of the folds of the mucous membrane makes breeding places for pathogenic germs. But, I believe these conditions are secondary and that germs are not concerned in the inception of a common cold and usually do not influence its course.

In conclusion, I would say that, although I have necessarily spent some time considering the merits of the microbic origin of a common cold, the main purpose of the paper was to present some plausible hypothesis of its mechanism on the ground of its inception being of vasomotor origin.

INTERSTITIAL PREGNANCY, WITH REPORT OF A CASE.*

By B. M. BAKER, M.D.,

NORFOLK, VA.

Ectopic gestation is a threadbare subject. In view of this fact and also that it is such a plain story from a standpoint of its history, etiology, symptoms, and the indication for treatment I hesitate about bringing the matter up again. But whereas ampullar and isthmic, the ordinary varieties, are so common, the interstitial is very uncommon, and therefore the temptation to report this case was greater and I believe will be well worth the few moments I will ask you to listen to me. This is given entirely from memory, the records of the case having been burned.

Interstitial pregnancy is a form of tubular gestation in which the ovum is fecundated in the portion of the tube which passes through the uterine wall. The text-books put it down as uncommon, and I was particularly surprised to find how little mention is made of personal experience with the condition by the authors of works on obstetrics. This led me to believe that the condition was even rarer than I had at first supposed. At the same time I cannot but believe that the cases are not always recognized, diagnosis being difficult at times. Then, too, it is perfectly possible for it to go on to a fatal termination and death ensue without anyone knowing of its existence, and, with the great antipathy of the human family to autopsies being held, I feel sure that many of these cases have had no record made of them.

The fact that the tendency of the ovum in its growth is to travel in the direction of the least resistance makes it more likely to rupture into the uterine cavity and be passed off through the natural passages as an ordinary abortion. This is another source of error in estimating the number of cases that actually do occur. Only the ones that happen to fall into the surgeons' hands, men capable of making nice diagnoses, are recognized and treated as the condition requires. These are accurately noted and reported, and they, together with the ones found at autopsies, make up the whole number so far as is known.

The ampullar form of tubular pregnancy is the most common, the isthmic next, and the interstitial least common. The etiology of all of these conditions is the same, and, although there is some obscurity about it, authors in general are agreed as to the one etiological factor, and that it is due to some inflammatory condition of the mucosa which prevents the natural passage of the ovum through the tube to the uterine cavity, and so fecundation takes place before it arrives there. The pathology is about the same in all tubular pregnancies—there is little room for growth and development of either the ovum, placenta, or membranes. The decidua is replaced by hyperplasia of the tubular tissues, including the mucosa and muscular coats, forming a sort of pseudodecidua, the uterine extremity of which has been seen to be open and in direct connection with the uterine mucosa. In the interstitial variety there is a greater hypertrophy in the uterine muscle, in its effort to hold and enclose the growing ovum. The broad ligament also encloses it at times. When the fetus grows so large that the uterine muscle can no longer withstand the strain rupture takes place in one direction or another, into either the uterine or the general peritoneal cavity. The symptoms of this condition are practically those of all tubular pregnancies with some others in addition: disturbed menstruation, pain, and the presence of a tumor. In addition to these symptoms there are, of course, the ordinary symptoms of pregnancy: nausea, physical development, breast symptoms, etc. With the bloody discharge there is sometimes also an expulsion of the decidua as a whole or in pieces. The difficulty of differentiating from physical signs alone can be easily appreciated. With the other symptoms present, and a decided increase in the size of one horn of the uterus rather than the other, or the body as a whole, would aid one in making out the condition clearly before rupture took place, and give him the opportunity to

*Read at the meeting of the Seaboard of Virginia and North Carolina Medical Society.

apply the indicated remedy. The condition could easily be confounded with ovarian tumor or a fibroid degeneration of the uterine body or a blood or pus tumor of the tube. The possibility of a double pregnant uterus may be taken into consideration, but this is a rare condition. Main dependence, of course, is to be put on the train of symptoms previously mentioned.

I need hardly mention the gravity accompanying the existence of an interstitial pregnancy—for the child it is desperate, for the mother a most disastrous accident, the mortality being more than fifty per cent.

The story of treatment is a plain one. Break up the pregnancy as rapidly as possible in a way that seems to give the mother the best chance to live. If it is deemed wise to attempt to open up a way to the fetal tissues through the uterine mucosa, such an effort may be made, this being the solution attended with the least risk, but practically never followed by the surgeon.

Theoretically if one could be certain of the condition, modified cesarian section could be performed with an effort to save both mother and child, provided the child was viable. Practically I find no record of such a case. The treatment generally indicated in these cases is that given my patient, a detailed account of which follows:

V. D. was referred to me by Dr. L. D. Matthews; she was a young married woman, twenty-three years of age, light mulatto, having one child four years of age. She ceased menstruating for a month or two about five months ago, then started to do so irregularly, and at the same time began having distinct pain in the right side in the neighborhood of the right ovary. This was followed by a growing tumor, and this was accompanied by other signs of pregnancy. At first the physician took the condition to be one of ovaritis accompanying true pregnancy. Later, he suspected something more serious, and on March 15, now eighteen months ago, when I was operating for him, he mentioned that he had a young married woman who was pregnant, but that the tumor seemed to him to be too far on one side, and he would like me to see her on the following day. This I agreed to do, but at one o'clock A. M., before the next dawn arrived, I was summoned hastily by him to see the patient. I found her in a condition of profound collapse, with a history of having on the previous day walked several miles and having suffered a sharp shooting pain with a feeling of something having given away as she jumped from a car the evening before. The abdomen was tense, tender, and dull on percussion, expression anxious, face pale and bathed in cold perspiration, conjunctiva blanched, no radial pulse, and constant longing for water and air. I was not long in either determining the condition or seeking a remedy. By two o'clock A. M. she was on the operating table. The abdomen being opened, we found the abdominal cavity filled with blood, which had to be baled out with a pitcher. As soon as we could clear the field of blood the condition was easily made out. A five months' fetus was present in the abdominal cavity, attached to the ruptured uterus by the cord, the placenta still *in situ*, blood pouring out from every direction. Her condition looked almost hopeless. A casual survey of the field convinced me there was nothing to do to stop the flow of blood but to cut off the entire arterial supply by clamps, followed by ligatures. This was done as rapidly as possible; the uterus was removed, and the abdomen was closed hurriedly, the abdomen being left full of warm salt solution. Of course, this work was done very hurriedly because of the patient's condition; and because of that fact, also, with not quite the same precision as such things are generally done. But when we completed the work there was no sign of hemorrhage and the woman was still living, but with no radial pulse and a flickering heart, so feeble and rapid that it was impossible to determine its rate. The operation was done almost with no anesthetic. The patient was in the Trendelenburg position, oxygen was administered, intravenous saline solution given, stimulants by hypodermic and rectum. After the patient was removed to the ward, the administration of oxygen was continued,

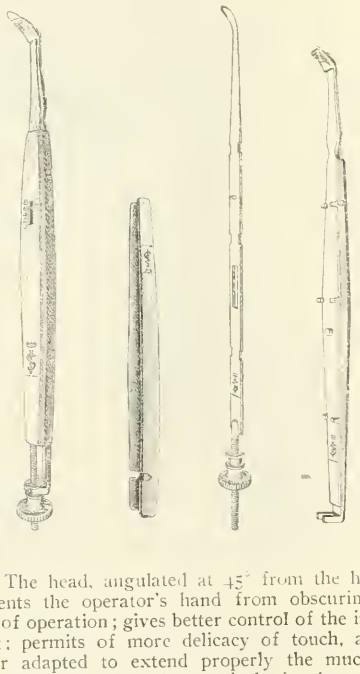
the head was lowered, and heat applied, the legs and arms were bandaged, and in an hour or two she rallied considerably. After several hours her pulse again began to fall off and to become more rapid and more feeble. I was hurriedly summoned to her, and felt very sure upon arriving that there must still be some bleeding point. She was taken to the operating room, and, with no anesthetic, the abdomen was reopened, and after a long search one minute spot was found where a drop of blood oozed forth about every two or three seconds. Still, to guard against any possible further trouble, I packed the field of operation from the end of the broad ligament on the one side to the same point on the opposite side with gauze, and left the end of this sticking out of the abdominal cavity just above the pubis. The wound bled no more. The

gauze was removed in forty-eight hours, and the opening was sewed up, and from that time on there was a steady improvement, until at the end of four or five weeks we found her well. The following fall she took up her position as a teacher in the public school. The illustration is from a photograph of the specimen.

THE AVERY NASAL SEPTATOME.*

By JOHN WAITE AVERY, A.B., M.D.,
NEW YORK.
ASSISTANT SURGEON, NEW YORK THROAT, NOSE, AND LUNG HOSPITAL.

The instrument here illustrated is devised for the rapid and accurate incision of the mucoperichondrium, and later of the cartilage in submucous resections of the nasal septum, for deflections of that structure. It has several new features which are a distinct advantage over both the straight scalpel or the right-angled knife with small blade, both of which are generally used for these incisions.



1. The head, angulated at 45° from the handle, prevents the operator's hand from obscuring the field of operation; gives better control of the instrument; permits of more delicacy of touch, and is better adapted to extend properly the mucoperichondrial incision, both superiorly in the septum and inferiorly down and out through the floor of the inferior meatus.

2. The blade is adjustable to cut a depth varying from 1/32 to 6/32 of an inch. By the screw on end of blade any change is quickly and accurately made. Having determined the thickness of the tissue to be incised, the blade is set at a corresponding length, and plunged in up to the head, which prevents too deep a cut, and so lessens the danger of perforation.

3. An indicator on the handle registers the length of the exposed portion of the blade, and hence the depth of the incision.

The septatome consists of three simple parts which are easily exposed for cleaning and sterilizing, and can be quickly reassembled. It is light and well balanced. The Kny Scheerer Company of New York have well embodied my ideas in the instrument here described and illustrated.

Mastoiditis in Infants.—G. Nové-Josserand and Maurice Jacod describe mastoiditis in the infant as of frequent occurrence and appearing suddenly without many premonitory symptoms. An abscess appears superficially without much pain or fever. The condition is predisposed to by states of general malnutrition, infectious diseases, and tuberculosis. The abscess pushes forward the auricle. The mastoid process is much more simple than in the adult, having from one to three large cells. The Eustachian tube is short and widely open so as to allow of easy infection from the naso-pharynx. Otitis, adenoids, and naso-pharyngeal catarrhs are the immediate cause, the form of microorganism being unimportant. The prognosis is good except in tubercular cases. The treatment consists of evacuation of the abscess, removal of diseased bone, and drainage.—*Archives Générales de Chirurgie.*

Treatment of Diphtheria.—In cases marked by severe vomiting and cardiac depression Rolleston has suggested the administration by mouth or rectum of adrenalin chloride in camphor water. Commenting on the frequent inadvisability of giving anything by mouth under the conditions referred to, F. G. Crookshank advises the use of tabloids, each containing 1-100th of a grain of adrenalin chloride and 1-100th of a grain of sulphate of strychnine, to make solutions for hypodermic injection. One or two of these tabloids may be administered every two, three, or four hours according to the gravity of the case; the action of the adrenalin appears to be sustained by the strychnine, which, of course, has its own special value in diphtheria, and the treatment can be continued and carried to a happy issue when neither mouth nor rectal administration is possible. The method is of service even in cases admitted in a desperate condition, but its greatest value is displayed when the administration of the two drugs is commenced immediately that vomiting or cardiac irregularity is noticed. The author makes it a part of the daily routine that immediately on the occurrence of vomiting all food, medicine, and throat treatment are stopped and adrenalin and strychnine be at once given hypodermically. —*The Lancet.*

Cirrhosis and Polyneuritis.—A. Porot and J. Froment tell us that cirrhosis of the liver and polyneuritis rarely develop with the same parallelism and intensity. They result from excessive alcoholism, mainly in females. From the beginning these patients have symptoms referred to the liver which are alarming. We have enlarged livers, including hypertrophic fatty cirrhosis, or pale yellow liver. There is always enlargement of the liver of moderate amount. Ascites is rare; ictperus is sometimes noted; digestive troubles and hemorrhages are prominent symptoms. The neuritis predominates in the lower extremities, and is manifested by pain, weakness, vasomotor troubles, failure of the sphincters, and a marked psychosis. There are insomnia, hallucinations, mental confusion, and delirium. The prognosis is bad, most patients dying within a few months as a result of hepatic insufficiency.—*Revue Française de Médecine et de Chirurgie.*

Errors of Diagnosis in Supposed Tuberculous Arthropathies Occasioned by the Presence of Rheumatism or Hereditary Syphilis.—H. Barbier contends that the family history, past history, and physical condition of the child having a monoarticular arthropathies should be carefully inquired into before instituting anti-tuberculous treatment and condemning the little patient to a long course of immobilization and rest in bed. Such lesions occur in hereditary syphilis. Here pain is absent, there is no deformity except such as results from involvement of the epiphyses, no contraction of muscles, no atrophy. The presence of deformed teeth, palate, and nasal organs, and of interstitial keratitis should be sought for. The family history of arthritic diathesis should be inquired into and rheumatic treatment should be tried before deciding on the tuberculous nature of the swelling. The author gives illustrative cases.—*Annales de Médecine et Chirurgie Infantiles.*

A POSSIBLE HEMIC CAUSE OF CARCINOMA.

The mystery of cancer is seemingly impenetrable. In spite of the constant study and investigation being pursued by many acute and trained minds in all parts of the world, we appear to be no nearer an agreement regarding the nature of cancer, its etiology, or even, we may say, its treatment, than we were ten or twenty years ago. The teachings of Cohnheim and Virchow and Beard that the cancer cell is an embryonic rest which in some way becomes stimulated into growth is still held by many; not a few regard the cancer cell as itself a parasite, while others consider it to be simply an epithelial cell stimulated to riotous growth by a microorganism or its toxin. And so we might go on with an enumeration of various and usually conflicting theories, the mere catalogue of which would fill pages. On one point nearly all investigators are agreed, however, and that is that cancer is at first a local disease and becomes generalized only after existing for an indefinite period. It is on this belief that the surgeon bases his insistent demand for early and radical removal of the growth.

The opposite theory, that cancer is a general disease and that the neoplasm is merely its local expression, occasioned by prolonged irritation, overfunctioning, or other factor, is held by a minority —a somewhat despised minority—yet there are some facts which speak in favor of it. One very strong argument is the fact, of which surgical writers always speak, and to which they attribute the very large percentage of failures to cure by operation, that it is almost impossible to recognize and remove the local growth early enough to prevent a generalization of the disease. Roswell Park is a believer in the parasitic causation of cancer and consequently that the disease is primarily local, yet he says, in a paper read at the International Congress of Surgery in Brussels last September (*Surgery, Gynecology, and Obstetrics* November, 1908): "Sad to say, cancer is a disease without a symptomatology of its own, and is to be recognized only by signs which are appreciated and duly recognized, in most instances, at a period too late to permit of the application of radical surgical measures. This aspect of the disease is one which has apparently attracted as yet but little attention, and yet it is the most important feature in the management of the disease, and offers alike the excuse for non-recognition as well as for failure in treatment." Such a statement argues in favor rather of a general disease with local manifestation than of the contrary, since it seems hardly probable that the local trouble would so often infect the general system before it has given any evidence whatever of its existence. Many writers also speak of the "precancerous stage" of malignant disease—a phrase having little meaning, if not that there is a stage preceding the appearance of a new growth in which the disease exists in the blood, but has not yet found local expression.

In a suggestive paper entitled "On an Excitant for the Leucocytes of Healthy Persons Found in the Blood Plasma of Patients Suffering from Carcinoma," published in the *Lancet* of January 16, C. J. Macalister and Hugh C. Ross of Liverpool relate certain findings which suggest the possibility that the cancerous tumor is merely the local manifestation of a disease dependent upon blood changes of a yet unknown nature. In the course of certain observations regarding the diffusion of stains into living leucocytes, Ross discovered that the presence of atropine sulphate caused marked and constant excitation of the cells, as manifested by exaggerated ameboid movements. At the same time Macalister had observed that patients with cancer often presented toxemic symptoms such as would be caused by some narcotic alkaloid, and he suggested that there might be in the blood some substance acting as a stimulant to normal cells and exciting them to abnormal growth. This suggestion led the experimenters to ascertain whether there might not be some such excitant to leucocytes in the blood of cancer subjects. The patient's citrated blood was centrifugalized and the citrated plasma mixed with one-eighth of its volume of the blood of a healthy person. The whole was left at a temperature of 37° C. for half an hour and then a minute drop was examined on a covered slide at a temperature of 20° C. In nine cases of carcinoma examined (and since the paper was written in November, a great many more) the leucocytes showed the remarkable ameboid movements, only more marked, which had been observed under the influence of atropine. In fifty control experiments with the blood of healthy, or rather of noncancerous, persons, the reaction was obtained in only two cases occurring in malarial subjects who had been taking large doses of quinine hydrochloride. Previous experiments had shown that this drug acted in the same way as atropine sulphate as an excitant of healthy leucocytes.

These are exceedingly interesting and suggestive experiments, pointing as they do the possibility of a hemic cause of carcinomatous growths. If further observation shows that the association with the neoplasm of this something in the blood, stimulating to the leucocytes, is constant, it will be a fact that cannot be disregarded in the study of carcinoma. If once the fact of the constant presence of this cell stimulant in the blood of cancer patients is established, it would seem to be a comparatively simple matter to determine its nature. The possibility of the cure of carcinoma by medical means, which

such a discovery would suggest, is also interesting to contemplate. But in the mean time Ross and Macalister have only established the probability that there is a cell stimulant in the blood of a patient with carcinoma; they have not shown whether its presence in the blood precedes the development of the neoplasm or whether it is formed in the tumor and washed out from it into the circulating blood.

THE RAT-FLEA THEORY OF PLAGUE.

The belief that the flea plays the most prominent rôle in the dissemination of plague has during the past few years so increased in strength that it has begun to be accepted on all hands as a proven fact. Indeed, it would not be exaggerating if it were said that it is now generally taken for granted by the medical profession as a whole throughout the world that the rat-flea is the main factor in the spread of plague. It assuredly is true that the theory is most plausible, and further than this proofs do not appear to be wanting in its support, while coincidence points in a like direction. Nevertheless, although the condemnatory evidence brought against the flea is very strong, and although the case against the insect almost seems to be conclusive, it is not well on this account to close one's ears to a consideration of the other side of the question. To fight plague successfully its originating cause and means of propagation must be definitely known.

At a meeting of the British Society of Tropical Medicine and Hygiene, held in London on December 18, 1908, Dr. W. C. Hossack read a paper on the present position of the rat-flea theory of plague, with recent observations in Calcutta. It is needless to say that it is in India, for very obvious reasons, that researches into the causes of plague have been carried on most extensively and carefully. To the result of investigations in India we are indebted for the greater part of our knowledge of plague, and it is in that country the rat-flea theory has been established. Dr. Hossack therefore said that he wished to put the other side of the question, the facts of which were gathered from investigations made by him in Calcutta and by others in Bombay, before the matter was placed practically beyond dispute. In the first instance, Dr. Hossack showed that egregious mistakes had been made with regard to the identity of the rat said to be chiefly responsible for the spread of plague, and that the principal plague rat of Calcutta was one never dreamed of before—the Bengal rat, *Nesokia bengalensis; Mus decumanus,* the brown rat, also played an important part, while the rôle of *Mus rattus* was almost negligible. Now, former investigations appeared to have proved that *Mus rattus* was the particular species of vermin which spread the plague, and that the theory of the flea being the especial agency for the dissemination was due to the habits of *Mus rattus,* as compared with those of *Mus decumanus.* The former is a roof-haunting rat, liable when dead to drop its fleas on man; the latter a sewer and burrowing rat, which leaves its fleas on its demise in its burrows, whence they cannot attack man. Moreover, Dr. Hossack emphasized the fact that flea conditions were quite different in Calcutta from those found in Bombay; *Pulex irritans* was practically unknown; *Pulex cheopis* was found only in connection with cats and dogs; and though the rat flea occurred on rats in numbers comparable to those found in Bombay, neither it nor any other flea had been found in plague houses unless in exceptional cases and in insignificant numbers. As to the question. Does the rat flea bite man. Dr. Hossack, as the outcome of carefully conducted experiments, came to the conclusion that even of starved rat-fleas, only one in six would bite, and considering Veribitski had found by experiment that with very highly virulent plague no infection was likely to take place in a rat when the number of experimental flea-bites was less than five, then there must be sixty starved fleas on a man to produce the necessary ten bites, a man requiring at least twice as many bites as a rat to produce infection. Thus a man must have a very large number of fleas upon him to contract the disease by these means. So far as acutely infected houses in Calcutta were concerned, if the cases of plague therein were due to flea bites the houses should have been swarming with rat-fleas. But no fleas were noticed in these houses. Consequently, Dr. Hossack argues that, if Verbitski's conclusions that even for the rat a minimum of five bites was necessary be accepted, then it followed that the rat-flea could play only an occasional and unimportant part in human infection.

The Bombay Advisory Committee on Plague have maintained in all their recent reports that the essential agent in the transmission of plague to man was the rat-flea, and it has seemed that they had ample cause for their conclusions. Dr. Hossack himself confessed that he had brought forward no positive theories, because his convictions were negative, so it may still be said that the flea-borne theory of plague holds the field. On the other hand, it is wise not to accept theories of the causation or propagation of disease until they have been absolutely shown to be correct.

The Dangers of Mercurial Injection.

The possible dangers that attend any therapeutic or diagnostic measures cannot, of course, be used as an argument for giving up such measures if the benefit of them is surely established for the great majority of instances in which they are used. For example, the fatal result that has sometimes followed the insertion of a needle into the chest for the purpose of exploring the pleural cavity for the presence of pus or of a nonpurulent effusion cannot be used as an argument against the use of this very valuable diagnostic procedure; nor can the more frequent fatal or serious results following the removal of such effusions by means of aspiration be looked upon as contraindicating the use of this method of treatment in preference to leaving the fluid in the cavity, with the hope that spontaneous absorption may take place. But the possibility of such accidents should be looked upon as a sufficient reason for telling the patient or his relatives that such procedures are not completely devoid of danger, as well as for using every known precaution in carrying out the simple operations required. An-

other therapeutic method that has been fast gaining in popularity in the last few years is the intramuscular injection of mercurial salts in the treatment of syphilis, little thought being given to the possible dangers connected with this method. Yet a review of the fatalities and grave accidents that have occurred in such treatment, published by Lassere in the *Annales de Dermatologie et de Syphiligraphie* for December, 1908, shows that seventy deaths have been ascribed to the procedure by various syphilidologists and that over one hundred serious accidents have likewise been reported. Injections of calomel and of the gray oil of the French have most deaths to answer for, thirty-eight fatal cases having been reported after the use of these preparations. Fatalities have been somewhat more common among female patients and among such cases in which unusually large doses of the drug were administered. However, the number of deaths and of serious accidents in other patients, in whom the usual dosage was employed, shows that there are dangers inherent in this method of medication, though, of course, these dangers are greatly multiplied by the failure of the physician to regulate the dosage carefully or take into consideration the condition of the heart and of the kidneys in patients who have come with a special complaint not depending upon these organs. It is probable that the figures published by Lassere represent but a small number of the fatalities that have occurred, as many of these are not reported or are considered to have been caused by other factors. Seventy deaths, however, is a number large enough to put every one employing deep injections of mercury on his guard and to show the advisability of telling patients that some danger beyond the power of the physician to obviate is present with this method of medication.

Typhoid Meningitis.

Typhoid bacilli are devoid of pyogenic effects in their usual localization in the intestinal tract with the production of the series of symptoms which we group under the term typhoid fever. Indeed, Mallory has quite conclusively shown that the toxins produced by the bacillus in this situation cause a productive inflammation, the swelling and the increase in the cells surrounding the intestinal ulcers produced by the bacilli explaining very well the phases in the gradual development of such ulcers from gangrene because of a diminution of the blood supply. That the same bacillus, however, may have a direct pyogenic effect seems to be shown by a case reported by Southard and Richards in the *Journal of Medical Research* for December, 1908. The patient, who was a paretic and under constant observation in an asylum, succumbed after a week's acute illness to a disease which on post-mortem examination proved to be purulent cerebrospinal meningitis complicated by bronchopneumonia. No typhoidal lesions were found in the intestines, but a bacillus isolated from a swollen mesenteric lymph node proved to belong to a typical strain of this organism. The exudate found in the meninges contained polynuclear leucocytes in great numbers, a fact which made the discovery of the typhoid bacillus as the cause of the meningitis very surprising. The authors experimented with animals in trying to produce effects similar to those observed by them in their patient and succeeded in producing inflammations of the meninges, with exudation of polynuclear cells, in guinea-pigs. They, therefore, put forth the hypothesis that typhoid bacilli may produce two very different effects, one of them consisting of the typical proliferative phenomena that take place in the intestinal lesions of typhoid fever; the other of a pyogenic action, which is perhaps due not to the soluble toxins produced by the bacilli, but to the endotoxins set free by the destruction of the bacilli at the side of the infection.

A New Vivisection Peril.

Argument, such as it is, vituperation, and misrepresentation having failed to abolish entirely, although they have seriously hampered scientific investigation in Great Britain, an ingenious Irish anti, possessed of the faith which moves mountains, has devised a new plan to save the lives of guinea-pigs by taking those of physiologists. According to a dispatch in *The Sun* of recent date, this lady, Cowan by name, has sent a circular to the leading surgeons and physiologists of the United Kingdom, warning them that she intends to accomplish their removal through the agency of prayer. The circular says that she had decided first to procure thus the death of Dr. Stirling, professor of physiology at the University College Hospital of London. But "it seemed unfair to give such a stab in the dark," so she made her petition more indefinite, leaving it to the Almighty to choose the victim. She besought Him therefore to remove, if in accordance with His will, the man most likely to cause future suffering to innocents by experiments. About a fortnight later a vivisectionist died. The gentle lady is now assured that she has the approval of Heaven in her righteous undertaking, and warns the recipients of the circular that she will continue to pray against them. There is not the slightest doubt that she will succeed if she only has perseverance and that in time all those who are now working for the saving of human life will die.

News of the Week.

Harvey Society Lecture.—The eighth of the present course of Harvey Society lectures will be delivered by Dr. Philip Hanson Hiss, Jr., on Saturday evening, February 6, at 8:30 o'clock, at the Academy of Medicine, 17 West Forty-third street, New York. Dr. Hiss will speak on "Some Problems in Immunity and the Treatment of Infectious Diseases."

Medical Expert Testimony.—The New York Bar Association in convention at Buffalo recently adopted the report of its committee on medical expert testimony. The report was accepted only after long argument and considerable opposition. After protesting against "the commercialization of scientific knowledge," the report pleads for the insuring of such conditions that expert witnesses, without regard to anything but justice and truth, may give their testimony without bias and without being subjected to improper cross-examination. A proposed statute provides that the justices of the Appellate Division shall designate not less than ten and not more than sixty physicians in each judicial district who may be called as medical expert witnesses by the trial court or by any party to a civil or criminal action; that when so called they shall testify and

be subject to examination and cross-examination, as are other witnesses; and that they shall be paid out of the county funds, the amount of the fee to be decided by the trial judge.

New Emmanuel Movement Rules.—Because of criticism of their work by medical men and others interested, and at the suggestion of an advisory board of physicians, the clergy of Emmanuel church, Boston, have adopted a set of rules designed to bring the physician and the minister into closer cooperation. The rules provide that no person shall be treated except with the approval of and after thorough examination by his family physician, whose report shall be filed with the clergyman's records: that no patient shall be referred to a specialist or assistant except with the advice and consent of his own physician: and that any patient not under the care of a physician must consult one before receiving instruction at Emmanuel church. It thus rests with the physicians to decide whether or not a patient shall be referred to a neurologist or other specialist, and which patients, if any, are suitable for moral and religious reeducation.

Opium Bill Passed.—The Senate on January 26, passed a bill forbidding the importation of opium into the United States except for medicinal purposes, and then only under strict regulations to be prescribed by the Secretary of the Treasury. All other forms of opium, smoking opium, or any derivative of opium, are absolutely shut out. Possession of the forbidden drug, it is expressly stated, shall be deemed sufficient evidence to convict, and offenders may be punished with two years imprisonment and a fine of $5,000. It was thought important to enact this legislation before the meeting of the international congress at Shanghai in February.

Royal Radium Institute.—London is soon to have a Royal British Radium Institute, in which research work will be carried on, and to which a medical department will eventually be attached for the treatment of cases to which experiment may show treatment by radium to be applicable. The work will probably be carried on with the help of the Imperial Cancer Research Fund. The council of the new institute will include Sir Frederick Treves, surgeon to the king, Sir William Ramsay, and Joseph John Thomson, professor of physics at the Royal Institution.

Death Rate in New York.—For the week ending January 23, the death rate in New York was 17.13 per thousand, the total number of deaths being 1,499. For the corresponding week of last year the rate was 17.80, and the total number of deaths 1,510. A slight increase was noted in the number of deaths from measles, bronchitis, and heart disease, while there was a decrease in the number from tuberculosis and pneumonia.

Less Typhoid Fever in New York.—A new record for typhoid fever was established in the Borough of Manhattan last year, according to the figures of the Department of Health. During the year 1,452 cases were reported, 256 of which were fatal. For the preceding year the figures were 2,387 cases with 372 deaths. While admitting that this reduction may be only accidental, the department hopes that its efforts in spreading information concerning the causes of the disease and the methods of prevention, may have had some effect. It is also suggested that the information which is contained in the pamphlets sent out by the department may have influenced the public to be more careful in its selection of summer resorts.

Smallpox in Central America.—It is reported that twelve thousand cases of smallpox are under treatment in Guatemala City and its environs where the disease has been epidemic for some months. Vaccination has been made compulsory and efforts are being made to protect all persons in the infected district. From Jalapa, the capital of Vera Cruz, Mexico, sixty-three cases were reported on January 27, with eleven deaths.

Low Birth Rate in Vera Cruz.—The reproach of race suicide, thrown off by France, has descended upon the city of Vera Cruz, Mexico, where during 1908 the records show 872 births and 2,116 deaths, 451 of the latter being due to tuberculosis.

Yellow Fever in Barbados.—An epidemic of yellowfever is reported from the island of Barbados. Up to January 29, twelve deaths had occurred, and a strict quarantine against the island is being enforced in neighboring ports.

Death from Forceps-retention.—A woman has just died in Philadelphia in consequence of the retention of a pair of forceps in her abdomen at the time of an operation some ten years ago. The cause of the difficulty was not discovered until an *x*-ray picture was taken recently, but the operation for relief terminated fatally. The surgeon who operated originally has since died.

Ferryboat School.—The old ferryboat "Middleton" has been added to the property of the Board of Education of New York, and will be moored at the foot of East 100th street to be used as a school for tuberculous children.

Prize for a Cure for Tuberculosis.—A bill has been introduced into the Pennsylvania Legislature offering a prize of $50,000 for the discovery of a cure for tuberculosis to be as effective as the antitoxin of diphtheria.

Tuberculosis Exhibits Planned in Chicago.—Traveling tuberculosis exhibits are the latest educational propaganda announcement of the Chicago Tuberculosis Institute. Business places in widely scattered sections of the city will be used for the displays, which will consist of posters filled with statistics and other information pertaining to the character, symptoms, and danger of this disease.

Dr. Bull's Condition.—The following bulletin concerning the condition of Dr. William T. Bull, who has been seriously ill for some time, was issued by the attending physicians on January 27. "Owing to the continued erroneous and misleading reports concerning Dr. Bull in certain newspaper articles and to the fact that these reports are arousing false hopes in the minds of many sufferers from cancer throughout the country it seems wise to issue the following statement: Dr. Bull's general condition and the rheumatic complications have improved sufficiently to warrant his departure for the warmer climate of Savannah in the near future. The original growth which was the real cause of his illness has never been cured." Dr. Bull is now near Savannah, Ga.

Medical Journals Merge.—The *Indiana Medical Journal* and the *Central States Medical Monitor* will merge in February under the title of *The Indianapolis Medical Journal*. Dr. S. E. Earp will continue as editor, and Dr. A. W. Brayton, for-

merly of the *Indiana Medical Journal*, will be a member of the editorial force.

Gifts to Charities.—By the terms of the will of the late Mrs. Catherine Conant of Newark, N. J., $5,000 each is given to the Lowell General Hospital at Lowell, Mass., and the Homeopathic Hospital of Essex County at Newark. The Hospital of Women and Children at Newark receives a share of the residuary estate.

Under the will of the late Mrs. Samuel Mather of Cleveland, Ohio, the Lakeside Hospital of that city receives an income of $6,000 a year.

Mount Sinai Hospital, New York, receives $3,000, and the Presbyterian Hospital $1,000, by the will of the late Charles Mayer, of that city.

The Presbyterian Hospital has also received a gift of $2,000 to complete the endowment of a bed from the estate of Mrs. E. L. Lathrop.

The VIII International Congress of Hydrology, Climatology, Geology, and Therapy by Physical Agents.—This congress will meet in Algiers, April 4 to 10, 1909, coinciding with the celebration of the fiftieth anniversary of the School of Medicine of the University of Algiers.

The Worth County (Ga.) Medical Society, at its meeting on January 20, elected the following officers: *President*, Dr. W. C. Tipton; *Vice-President*, Dr. W. K. Stewart; *Secretary-Treasurer*, Dr. G. G. Lunsford; *Delegate to State Medical Association*, Dr. V. P. Stevens.

Chicago Laryngological and Otological Society.—At the annual meeting of this Society, held January 26, the following officers were elected: *President*, Dr. Henry Gradle; *Vice-President*, Dr. Chas. M. Robertson; *Secretary-Treasurer*, Dr. F. Gurney Stubbs; *Councilor*, Dr. A. M. Corwin.

Chicago Neurological Society.—At its meeting held January 28 the following officers were elected: *President*, Dr. L. Harrison Mettler; *Vice-President*, Dr. D'Orsay Hecht; *Secretary*, Dr. Peter Bassoe; *Treasurer*, Dr. Geo. W. Hall; *Councilor*, Dr. Sydney Kuh.

Illinois Branch of the American National Red Cross.—This branch will soon organize a first-aid legion on a military basis. Dr. Gustavus M. Blech has been appointed director-in-chief by Dr. L. L. McArthur, Chairman of the Executive Committee.

Milwaukee Physicians' Association.—At the annual meeting of this society, on January 19, the following officers were elected: *President*, A. R. F. Grob; *Vice-President*, E. Wells Kellogg; *Treasurer*, Henry J. Gramling; *Secretary*, A. A. Cooper; *Board of Censors*, P. Langland, H. C. Werner, F. W. Riehl.

The Brown County (Wis.) Medical Society, at its annual meeting at Green Bay, recently, elected the following officers: *President*, Dr. C. J. Chloupek; *Vice-President*, Dr. H. P. Hendricks; *Secretary and Treasurer*, Dr. R. H. Sweetman; *Censor*, Dr. A. W. Slaughter.

The Southwestern Minnesota Medical Society.—The twenty-first annual meeting of this society was held on January 19. Election of officers resulted as follows: *President*, Dr. A. H. Brown, Pipestone; *Vice-President*, Dr. A. D. Williams, Wilmar; *Secretary and Treasurer*, Dr. Emil King, Fulda; *Delegate to State Convention*, Dr. W. D. Beadle, Windom. The next meeting will be held in Slayton in July.

The Oxford County (Ont.) Medical Association held its annual meeting at Woodstock on January 22. The following officers were elected for the ensuing year: *President*, Dr. Green of Embro; *Vice-President*, Dr. Angus McKay of Ingersoll; *Secretary*, Dr. Brodie of Woodstock; *Treasurer*, Dr. Neff of Ingersoll.

The Nashua (N. H.) Medical Association, at its annual meeting on January 22, elected the following officers: *President*, Dr. A. S. Wallace; *First Vice-President*, Dr. Henry O. Smith; *Second Vice-President*, Dr. W. E. Reed; *Secretary*, Dr. Eva M. Locke; *Treasurer*, Dr. A. L. Wallace; *Historian*, Dr. C. B. Hammond; *Executive Committee, Chairman*, Dr. S. S. Dearborn, Dr. C. F. Nutter and Dr. Mary Sweeney.

Obituary Notes.—Dr. Francis Joseph Rogers, City Health Officer of Stamford, Conn., died at his home in that city on January 27, after a short illness, aged sixty years. Dr. Rogers was graduated from Holy Cross College in 1870, and from the medical school of the University of Pennsylvania in 1873. In 1877 he settled in Stamford, where he had since practised.

Dr. Arville A. Oleson, until recently of Axtell, Neb., was killed in a railroad accident at Glenwood Springs, Col., on January 15. Mrs. Oleson was also killed and their young son was severely injured. Dr. Oleson, who was a graduate of the Rush Medical College of Chicago, was on his way with his family to Spokane, Wash., where he intended to practise.

Dr. James Fenton Bryant of Franklin, Va., died at his home on January 16, aged 67 years. Dr. Bryant, after serving throughout the Civil War in the Confederate Army, was graduated in medicine from the University of New York, and had practised in Franklin for many years.

Dr. Charles Francis of Reno, Nev., died of tuberculosis on January 14, aged 33 years. He was graduated from the medical department of Northwestern University in 1901.

Dr. William Aitchson of Ortonville, Mich., died at his home, on January 10, after a brief illness, aged 62 years. He was graduated from the University of Michigan in the class of 1873, and was a charter member of the Oakland County Medical Society.

Dr. J. H. Donald of Piedmont, S. C., died suddenly while attending a patient, on January 23, aged 55 years. He was graduated from the Charleston Medical College in 1875.

Dr. John L. Howard of West Baden, Ind., died at his home on January 22. Dr. Howard was a graduate of the University of Virginia, and was at one time a member of the Faculty of the University of Louisville.

Dr. Francis S. McNamara, the oldest practicing physician of Milwaukee, Wis., died on January 22, after several months' illness. Dr. McNamara was born in Ireland and received his medical education there, coming to this country in 1845.

Dr. Thomas Stewart of Carlisle, Pa., died in Cleveland, Ohio, on January 28, at the age of 50 years. He was graduated from the Western Reserve University Medical College in the class of 1874.

Dr. Ira G. Stone of Kingfisher, Okla., died at St. Francis' Hospital, Wichita, on December 31, aged 54 years. He was a graduate of the Rush Medical College of Chicago.

Correspondence.

THE TRANSFER OF MORIBUND HOSPITAL PATIENTS.

To the Editor of the Medical Record:

Sir:—In your issue of January 30, 1909, in an editorial upon "The Transfer of Moribund Hospital Patients," appears a censure of the alleged "practice" of transferring "moribund hospital patients" in ambulances to Bellevue Hospital, and the accusation is made that this is done "in order to keep the mortality statistics within limits pleasing to the trustees and to the contributors of money to the institutions," and further, "that so long as there are any officers of private hospitals whose eyes are fixed on the annual report, and whose hearts are unmoved by the sufferings of the dying, all the hospitals in the city must lie under the suspicion of favoring such practices." The second of the three cases which are cited in support of this grave charge was that of a patient received in a private hospital suffering from fractured ribs and chronic alcoholism. He lived for seven days after transfer to Bellevue Hospital, when autopsy disclosed a fracture of the base of the skull which had given so few symptoms that its existence was unsuspected at either institution until revealed by the post-mortem findings. It cannot fairly be claimed that death was due to transfer in such a case, or was accelerated by it.

It is a misapprehension that those officially connected with hospitals are desirous of exhibiting a low death rate; in fact it is much more for their interest to retain moribund patients in the hope of subsequently deriving the scientific data which autopsies may afford. I have lately asked the superintendents and managers of a half-dozen hospitals what their death rate was, and how it had compared with other institutions, and in not a single instance were they able to inform me. In twenty-five years of official connection with a number of hospitals, both private and public of this city, I have never known of a single instance in which the death rate of the institution was considered in relation to the transfer of a patient, although such allegations are being made constantly by unjust and ill-informed critics. The total number of patients transferred in New York by ambulances exceeds 50,000 yearly. This work is done by sixteen municipal and twenty-eight private ambulances. That an occasional wrong diagnosis should be made, or that an occasional sudden death should occur among so many sick persons, may reasonably be expected, without attaching special blame to anyone. The vital statistics of the city show that among a like number of seemingly well persons, the incidence of sudden death (exclusive of accidents) is 3 per cent. The private hospital ambulance system is maintained in several institutions at a cost of more than $5,000 per annum, yet they have been so persecuted by unjust criticism as their only reward, that they are seriously meditating abandoning this humane part of their public service. The Roosevelt Hospital has already published its intention of giving up its ambulance service for general public work, and another equally representative institution has the same action under discussion. It is to be hoped that such radical measures may hasten the municipal control of the entire ambulance system of the city, with a central bureau, or "clearing house," and local receiving stations, such as exists in Berlin, and has been recommended by the Mayor's Hospital Commission for incorporation in the revised charter.

The public have grown to look upon the ambulance system in an entirely wrong light, with the result that it is greatly overtaxed. Ambulances are demanded with instant service for most trivial ailments or for patients perfectly well able to find their own way into hospitals or dispensaries. For example, in an ambulance record of a single day, taken at random, I find the following calls entered: "Incipient tuberculosis," "destitution," "abrasion of face," "gonorrhea," two cases of "alleged insanity." On another day are included "hysteria" and "epistaxis." This institution answers an average of ten calls per diem, or 3,650 a year. Not a few of the cases which have brought criticism upon hospitals in the past, as being inhumanely transferred were patients suffering from delirium tremens, but very few of the private hospitals have been constructed with any isolation rooms for segregation of such noisy patients. If the patients be admitted to the general wards they disturb everyone else who is very ill, and besides, for their own safety, there are inadequate means for their restraint. Unfortunately, these patients sometimes die quite suddenly, when apparently previously strong, and although transference in an ambulance does them no harm, if they happen to die within twenty-four hours, it is liable to beget censure from those unfamiliar with all the existing conditions. In other cities the ambulance work has not attempted to cover so large a field, and the public do not demand infallibility. For example, in Cleveland and one or two other cities, it is fairly conducted by the private enterprise of the undertakers (!) who own and operate the "busses," and in Rome, Italy, when a street accident occurs the police are permitted to seize any passing carriage, even that of the King, for temporary ambulance service, thus obviating all delay.

I trust, Mr. Editor, that in the interest of fairness you will find space for this refutation of your strictures upon hospital management which has already suffered so much injustice from the sensational lay press as to feel compelled to abandon, in part at least, a work which for many years has accomplished great good for the whole of the local community.

W. Gilman Thompson, M.D.

34 East Thirty-first Street, New York.

[That the practice is not only "alleged," but actually exists, is within the personal knowledge of the writer of the editorial note which Dr. Thompson criticises. One of the instances referred to was not an ambulance case, but that of a patient in the medical ward of one of the private hospitals of this city. He was suffering from advanced nephritis, and had had a meningeal hemorrhage. He was in a stuporous condition, not delirious, and not a cause of disturbance in the ward. He was moribund, but through the prompt action of the authorities he did not "die in the house." Until such occurrences are made impossible it is the duty of physicians and philanthropists to do what in them lies to root out the evil.—Ed.]

THE STATE CONTROL OF VENEREAL DISEASES.

To the Editor of the Medical Record.

Sir:—There has been brought to my notice a letter printed in the Medical Record under date of January 16, written by Drs. Valentine and Townsend, in which attention is drawn to the movement to control the venereal diseases in Iowa. The prominence of these gentlemen in the profession and in the treatment of the venereal diseases, together with the unquestioned sincerity of their wish to protect the physicians and the citizens of Iowa from unwise legislation, will attract the attention of the medical profession and command consideration of their views. My name has been courteously mentioned in the letter, and I am credited by the gentlemen with a share in the work of preparation for legislative control of the venereal diseases in this State. The reasons set forth will be an excuse, I trust, for placing before your readers a brief outline of the steps taken for the control of these diseases, and a defense of the bill that has been subjected to criticism.

As a result of the circulation during the past three years of authenticated statements of ravages of the venereal diseases, endorsements looking to the passage and enforcement of a protecting law have been received and are about to be placed in the hands of the General Assembly. The endorsements have come from many sources, among those not mentioned by your correspondents being the Iowa State Medical Society, the State Society of Medical Women, and the Iowa State Dental Society. It should not be inferred that the societies, colleges, and conventions have approved of the bill in its present form, for it has not been submitted to them. However, the president of the State Medical Society and the president of the State Dental Society have fully accepted the measure and will work for its passage. It may be of interest, and I hope not irrelevant to state here, but one person in the State has, so far as I know, advanced an objection to the ultimate legal control of the venereal diseases. The Women's Christian Temperance Union has worked steadily for two years to introduce warning literature into homes in every county in the State, and has secured the signatures of a large number of medical men to a petition for an effective law. This society will introduce the measure into the legislature solely for the purpose of protecting the homes, and of helping to control Iowa's most destructive plague.

The draft of the bill to be submitted provides for a commission consisting of three regular practicing physicians in each county, to be appointed by the District Courts, to constitute a County Board of Health, to which all cases of venereal diseases shall be reported. This board will be required to fix a bond ranging in amount from a merely nominal sum to five hundred dollars, which will insure that the person afflicted with a venereal disease in an infectious stage shall remain under efficient medical control, and so conduct himself that he will not inflict his disease upon another person. Upon receipt of a certificate from the

physician in charge of the case stating that the patient has passed the infectious stage he shall be released from the conditions imposed by his bond and the record of his case be wholly destroyed by the County Board of Health. It will be seen from this that knowledge of cases reported to the County Board of Health will be confined to a small number of responsible physicians, and that it is the purpose of the law to quarantine only those who will persistently and flagrantly disobey the regulations, which the law provides shall be imposed by the State Board of Health.

With the above statement of fact in mind I am unable to connect the criticism of Drs. Valentine and Townsend, relating to section one, with disruption of families. Nor can it be conceded that venereal diseases will be treated by less competent men than those now handling them, for there are in the eyes of the law no persons practising medicine in Iowa that are not properly qualified to do so.

The criticism of section two resolves itself into the recognition of the contagious stages and the time at which the patient can be discharged without danger of infecting others. In reply to this I will say, first, that the State bacteriologist, Dr. Albert, who favors proper legal control, has not advanced this objection and informs me that an expenditure of but fifteen hundred dollars will enable him to add venereal examinations to his present duties. Second, the long and satisfactory experiences of Germany, Norway, and Denmark have demonstrated the feasibility of this control. Would any one exempt diphtheria from control because it is even less possible to demonstrate the day or week when it is safe to discharge the patient?

The criticisms of sections six and seven are sufficiently answered in a preceding paragraph.

As section ten refers solely to the prohibition of druggists and other unlicensed persons prescribing for these cases I do not feel that it is necessary to offer a defense of it.

Sections twelve and thirteen are practically identical with provisions now in force in Iowa for the control of other infectious and contagious diseases.

Section fourteen provides for a penalty in case any person shall knowingly transmit these diseases by intercourse to another person. This appears to me to be an obviously proper provision of the proposed law.

Drs. Valentine and Townsend truly state that premarital and extramarital coitus will be practised despite the passage of this law. It must surely appear that no especial effect upon the social evil is expected by the operation of the law for which we are asking. We believe, as they doubtless do, that this evil will come under gradual subjection through the normal evolution of social institutions. The sole object of the law is to control the most disastrous diseases we have, and we know of no reason why the intelligence and moral fiber of Iowa physicians and laymen cannot be relied upon for the enforcement of a beneficent law as well as can these qualities in the physicians and laymen of Norway and Denmark.

After an almost daily correspondence, lasting over a period of three years, the writer has to say that he has met with but two correspondents who have not favored at some time and in some way the legal control of the venereal diseases.

He has received much valuable advice and kindly encouragement, and takes this opportunity to thank all his friends, including his present critics, for their patient efforts to guide him.

G. Hardy Clark, M.D.

Waterloo, Iowa.

THE PROFESSIONAL SECRET IN RELATION TO VENEREAL DISEASES.

To the Editor of the Medical Record:

Sir:—In your issue of January 16, I note a letter from Drs. Valentine and Townsend anent proposed antivenereal legislation in Iowa. No doubt we all concur in the views expressed. However, I, for one, have reached the point where, under certain circumstances, regardless of damage suits or professional ostracism, I will not protect syphilitics or gonorrheics.

A young man was under my care for primary syphilis which rapidly developed secondary symptoms. I had given him complete instruction regarding the danger of communicating his infection to others. While mucous patches were present around his anus and in his mouth he married a pure and beautiful girl of twenty years. Six months later she was the victim of malignant syphilis. The divorce court gave her freedom from the man who contaminated her, and also made him free to infect another pure girl.

A young woman of lovely character, whom I had cared for from babyhood, asked me if it was safe to marry a young man who was also my patient. I replied yes. Two weeks later, in the effort to test his potency before marriage, the man acquired gonorrhea. In spite of strenuous opposition he married the girl during the acute stage of his disease. I have since operated upon his wife.

In a similar case another physician notified the girl's parents on the morning of the wedding day, thus preventing marriage. This doctor had previously endeavored to induce the man to postpone the ceremony but without avail. He then threatened to expose him and finally did so in spite of assurance of bodily injury. I honor the doctor.

A young woman whom I knew to be pure brought to me her lover on account of sore throat. Their wedding day was approaching. The man had secondary syphilis; his throat was badly ulcerated. He refused to postpone the marriage. I then told him to leave town within 24 hours or I would explain his situation to the girl. He left. Subsequently the girl married a decent fellow.

In cases where venereal disease is necessarily contagious I will protect the girl and not the man: first, of course, endeavoring to induce the man to afford the needed protection. Most men will do so, but all of us have met instances where they will not.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE MEDICAL OFFICER'S REPORT FOR THE COUNTY OF LONDON—THE DEPARTMENTAL REPORT ON INEBRIETY—HOSPITAL SUNDAY FUND—SLEEPING SICKNESS—A BACTERIOLOGIST FOR THE ROYAL HOUSEHOLD.

London January 15, 1909.

The report of the Medical Officer of the London County Council for the year 1907 has been issued this week. For the third year in succession the death rate has not exceeded that of any previous year. In 1905 and 1906 it was 15.1 and in 1907 fell to 14.6. The birth rate was the lowest recorded since registration was established, only 25.6. In the middle of the year the population of the county was estimated at 4,758,218. Overcrowding is a condition varying greatly in different localities and of course is associated with other circumstances. In Shoreditch there is overcrowding to the extent of 30 per cent. of the population; in Hampstead not above 6.4 per cent. In the former the death rate is practically twice as high, the phthisis mortality three times, and the infantile mortality twice as high as in the latter. Shoreditch is, says the Medical Officer, but a sample of a much larger population in London and elsewhere whose mortality is increased by causes which must be considered as largely preventable. The suffocation of infants in bed shows a progressively higher rate from the least to the most overcrowded localities. The epidemic death rate was very low—only 1.42. No death from smallpox. Those from measles, influenza, diphtheria, typhoid, diarrhea, and phthisis were all under the average, but scarlet fever and whooping cough were above. Estimates of homeless persons have been attempted and the result is about 1 in 2,000 of the population, and yet it is curious to note that on the night of the inquiry accommodation in the casual wards for 745 persons remained unoccupied, the total accommodation provided in London, which is sufficient for 1,882, being occupied by only 1,137 persons. There have been previous inquiries and it would seem that homeless persons are more numerous, unless perhaps the counting has been more careful. In 1904 on the night selected for inquiry the number was 2,000, in 1905 2,200 were found and in 1907 there were 2,400.

The report of the Departmental Committee on Inebriety and Reformatories was issued on [illegible] and will without doubt give rise to much discussion, for it is a most able and interesting production. The conclusions will not be accepted by all, but no one will deny that they are deserving of careful attention. The original reference was to inquire into the law relating to inebriates and report what amendments were desirable, but this was extended in August last at the request of the committee so as to include the question of treatment by drugs. Improbable as it seems that any such treatment would possess features which would warrant its incorporation, if possible, in a statute, the committee thought it right to communicate with the advocates of these vaunted cures. To embark upon a full inquiry into the comparative merits

of these treatments by drugs of secret composition and obscure action would serve no good purpose, and the committee calls attention to the fact that drugs cannot possibly supply the penal element present in all sentences to reformatories. It may be permitted to remark here that the committee could not be recognized as competent to judge of the value of drugs and that the medical profession has not been able to recognize any pretended "cure" as really efficacious.

The public has long been convinced that legislation as to inebriety has hitherto been a failure and that this is the conviction of the committee is obvious from their recommendation to pass an act repealing much of it, amending more, consolidating the remainder, and adding further laws of a restrictive kind. They propose to substitute the term inebriate for "habitual drunkard" throughout the consolidated law and offer the following definition: "An inebriate is a person who habitually takes or uses any intoxicating thing or things, and while under the influence of such thing or things, or in consequence of the effects thereof, is (a) dangerous to himself or others, or (b) a cause of harm or serious annoyance to his family or others, or (c) incapable of managing himself or his affairs or of ordinary proper conduct." It is recommended that the powers of local authorities as to inebriates be transferred to the Secretary of State, who should have power to remove an inebriate, with his consent, from one retreat to another.

Inebriates should be allowed to enter into a legal obligation before a justice of the peace to abstain from intoxicants for any period not less than a year. They might also apply to a justice of the peace for an order of guardianship, which would give the appointed guardian power to fix the residence of the inebriate, to prevent him from obtaining intoxicants, to submit him to nurses or attendants, and to warn sellers not to supply him. So far the attempt is a voluntary one on the part of the inebriate, but when this has failed or is refused it is recommended that a relative, friend, or a previously appointed guardian may petition a judicial authority to grant a compulsory guardianship or to commit to a retreat. The authority being satisfied that the case requires it, may issue an order to this effect, to operate for at least a year. Guardianship, even when compulsory, is a less severe measure than committal to a retreat. The judicial authority is to be empowered to require the inebriate to bear such expenses as he considers reasonable.

Another recommendation of great importance is that magistrates should have discretionary power to send to reformatories, in addition to or in substitution of imprisonment, all inebriates convicted before them of various offenses, *e.g.* neglect of or cruelty to children, attempted suicide, wilful damage, wounding not amounting to a felony, etc. Another far-reaching proposition is that the State should provide accommodation and maintenance of all inebriates committed by the courts, taking over such existing reformatories as may be suitable or adaptable to the scheme. Contributions may be enforced from the inebriate or those responsible for him. But the State must itself bear the cost of the destitute or very poor inebriates and of troublesome or undesirable inmates. Any person who has become a charge on the rates on account of delirium tremens is to be deemed an inebriate and may be proceeded against by the guardians to whom he has been chargeable.

It is recommended that any future legislation respecting drunkards should apply equally to drug takers.

The report has been received with no little satisfaction by leading members of the Society for the Study of Inebriety and of the temperance societies. Some of them are very enthusiastic, but they have yet to reckon with the difficulty of carrying any act through Parliament. A few persons timidly suggest the danger of restricting the liberty of the subject, but considering the interference with this liberty which has taken place in so many directions of late years, there is not much to be said in defense of the liberty of getting drunk and being a nuisance and a danger to others.

At the Royal Society of Medicine last week Dr. James Mackenzie gave a demonstration of his clinical polygraph, which had been used to record cardiac and other vascular movements. It consists of a small cup to apply over a pulsating part, fitted to a rubber tube connected with a tambour and a sphygmograph. The use of this led to the invention of an ink polygraph, by which tracings of indefinite length can be made with ink on a gradually unwinding roll of paper, moved by clockwork. Dr. Mackenzie showed a number of records and demonstrated the way in which they must be read. He then showed the method of using it on the human subject and stated the inferences he had drawn from the records. He must have been gratified with the reception given to his work, for all the speakers had a good word for it. Dr. Paul Chapman, who had used an instrument to record the cardiac beat, but not, as this new one, the radial pulse, believed it would be of great value. Sir Lauder Brunton, who had used various recording instruments, said this was the most convenient and was much less expensive than others. Sir J. Broadbent and Dr. Herringham, without accepting all the inferences put forward, accorded high praise to Dr. Mackenzie's work. Dr. T. Lewis had for twelve weeks been using the instrument and thought the examination of irregularly acting hearts was futile without it.

The Council of the Hospital Sunday Fund yesterday agreed that the general purposes committee should ask the Rev. L. S. Lewis to attend and state his views. He is the person who made an unseemly disturbance at the meeting of the constituents because no grant was given to the "Antivivisection Hospital."

The Belgian Colonial Minister has decided to establish six new hospitals for the study and treatment of sleeping sickness in the Congo.

Dr. Harold Spitta has been appointed bacteriologist to the Royal Household—a new office, the creation of which seems gratifying to the specialists, as indicating that bacteriology is becoming recognized as of practical value.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 21, 1909.

Some Aspects of Cystitis.—A. L. Chute presents a general description of cystitis both acute and chronic. The diagnosis of the latter variety is often difficult on account of the great similarity of the symptoms with those of chronic renal suppuration. Occasionally a kidney process that does not in the least involve the bladder may present, besides a turbid urine, more or less painful and frequent micturition. Renal processes involving the bladder to only a slight degree may give very marked bladder symptoms. Alkaline urine suggests (but does not prove) a bladder lesion. A urine that after sedimentation by gravity shows a finely turbid supernatant layer is said to point to bladder rather than to kidney suppuration. A bladder that will easily take a considerable amount of distention is against the probability of cystitis. A test of more value is that of comparing a specimen voided with a specimen collected by a catheter left in after the bladder has been washed perfectly clean. If the first few ounces collected after this washing are much less turbid than the voided specimen, the pus probably originates in the bladder; if, on the other hand, the specimen collected after the washing is as turbid as the specimen passed before, it is probable that the pus comes from the kidney. Cystoscopy is often necessary. We should trace every case back to its original starting point as the accurate determination of the predisposing cause will often enable us to predicate the result of therapeutic measures. While the treatment of acute cystitis is almost entirely general, that of chronic is almost entirely local. Nitrate of silver, 5 to 15 per cent., is our most useful drug for chronic ulcerations. The more advanced ulcerations call for putting the bladder at rest by drainage and suprapubic cystotomy. In the author's experience the opsonic treatment is of little value. He notes that the bacteria which may have started the process leading to chronic cystitis have no particular action in keeping up the tissue changes, with the possible exception of the ulcerations. The deep infiltrations and cell changes have become habit, so to speak, and go on automatically, but are no longer due to the mere presence of the organisms in the tissues. The irregular surface of the bladder lining forms a favorable place for them, but they have no real action in keeping up the process. Hence a diminution in their number would have no tendency to heal the process. The opsonic method may help acute cases, but such usually get well anyway. They generally arise from infection through the urethra. If the infection has would have no tendency to heal the process. The

latter may be subacute or chronic from the beginning. Tuberculous cystitis is always, in the author's experience, a secondary disease. The removal of the predisposing cause, which is generally a unilateral renal tuberculosis, will generally effect a cure.

The Value of Hemolysis in the Diagnosis of Carcinoma.—W. Whittemore has made a study of cancer tuberculosis, diabetes, various tumors other than cancer, and of a certain number of normal patients with reference to hemolysis, and also refers to the results obtained by other workers. In his own series of 109 cases, 39 normal individuals were listed. Of this number hemolysis occurred in 7, or 17 per cent. In 22 cases of carcinoma, it occurred in 8, or 36 per cent. It occurred in 50 per cent. of tuberculous cases examined and also in chronic empyema, Hodgkin's disease, tabes, paraplegia, general paresis, and once each in malaria and sarcoma. From these results the author believes that at the present time hemolysis is of no value in the diagnosis of carcinoma. As the process occurs in vitro in normal individuals and in diseases other than cancer, it would seem necessary to do a hemolytic test before transfusion. This is borne out by the occurrence of two deaths following transfusion.

New York Medical Journal, January 23, 1909.

Two Instances of the Simultaneous Occurrence of Hypernephroma and Carcinoma.—The histories of these two cases are given at length by G. B. Foster, Jr., and C. H. Gerhard. They regard the simultaneous occurrence as worthy of record and suggestive of a possibility of similar causation. One might easily fancy, however, the presence of some chemical stimulus or removal of some chemical restraint of growth operating at the same time upon the epithelium of the stomach and upon the cells of an adrenal "rest," or of the adrenal tissue itself. It is of interest to add that in the second case there were definite atrophic changes in the pancreas and that the well known rapidity of growth and the vegetative appearances of the cells in many hypernephromata have some importance if one thinks of malignant tumors as arising, according to Beard's recent theory, from trophoblastic cells. However, even if one were to acknowledge the existence of some degree of value in Beard's suggestion, the sharp difference between the simultaneously occurring tumors would argue against the general applicability of his idea, since, if both types of tumors arise from unused germ cells, the tumors should have been identical, whereas in each case they are distinct and the metastatic growths have followed the type, now of one, now of the other. The occurrence of bone in the hypernephroma of the first case is in line with the suggestion which has previously been made that these adrenal tumors are in reality of teratomatous type and adds somewhat to a restricted application of Beard's theory to this class of adrenal tumors. In further comment upon the applicability of Beard's theory, it may be said that while it is true there existed definite atrophy in the pancreas of the second case, and a slight grade of chronic interstitial pancreatitis in the first, the grade of these changes was by no means excessive or beyond that which is found in a large proportion of autopsies on subjects without any neoplastic formations whatever.

Incipient Tuberculosis of the Lungs and Its Diagnosis.—Gordon Wilson emphasizes certain points which have frequently been exploited in the literature of recent years. The main symptoms of the incipient stage are cough, hemorrhage, loss of weight, a moderate degree of malaise, night sweats, and fever. The author attaches but little importance to palpation. In percussion the finger should be held flat and very firmly against the chest wall. The blow should be given with the end of the finger—not the pulp—and it must not be allowed to rebound. We should percuss from the wrist and not from the elbow, and the percussing finger should be kept at a right angle. In listening for adventitious sounds and changes in respiratory murmur, three types of breathing should be used by the patient. (1) We should listen to the "danger zones" while the patient breathes naturally. A slight alteration in the character of the vesicular murmur together with a difference in the intensity of the breath sounds in corresponding areas should undoubtedly be put down as important evidence of disease, especially if backed by a suggestive history. (2) Get the patient to breathe deeply, but naturally, as one does after climbing a long flight of stairs. This way of breathing many patients will not do unless shown, but by doing it yourself, and telling him to breathe like you and with you, he soon does it in a satisfactory manner. This type of respiration will frequently "bring out" fine crepitant râles, and will make more clear the difference in intensity between the corresponding areas. (3) This is a modification of the breathing in 2, obtained by getting the patient to give a slight cough at the end of expiration, and then take a deep inspiration. This very frequently brings out râles that you are unable to hear by any other means, and by many is considered the most important of all auscultation methods in incipient tuberculosis of the lungs. To justify us in making a definite diagnosis we must have a suggestive history, bacilli in sputa, persistent physical signs in the lungs not accounted for by syphilis. A tuberculous invasion may simulate influenza, and it is such instances that tuberculin may be employed to settle the diagnosis. The author utters a word of caution with reference to the ophthalmotuberculin test. Corneal ulcers as well as severe reactions have followed its use.

Journal of the American Medical Association, January 23, 1909.

Tuberculin Treatment.—E. L. Trudeau considers neither the vaccination nor the toxin immunization theories of the tuberculin treatment of tuberculosis entirely satisfactory, owing to our, as yet, imperfect knowledge of the mechanism of tuberculous infection, and especially of acquired and artificial immunity. If we must have a working theory, however, and must decide between the two, he prefers for the present to hold to the conception of an immunity that is principally at least antitoxic as produced by the treatment, and to consider tuberculin habituation its essential feature and the best guide to dosage. This does not lead us to expect too much, and is, he thinks, more in accord with what we observe clinically as the result of treatment, and explains its very evident limitations. It is in accord, also, with experimental facts showing that only vaccinations with living cultures produce any real immunity, and not those with dead germs or chemical products derived from cultures. Accepting thus the toxin immunization conception as the guide to treatment, instead of measuring the degree of a questionable antibacterial immunity by the opsonic index, or attempting to produce it more empirically by a series of moderate reactions, the severity of which we can not in any way control, the main features of treatment, he says, would be: 1. To raise the degree of tolerance to tuberculin to the highest point attainable in each case by an almost imperceptible and long-continued progression in dosage. 2. To avoid general and focal reactions as much as possible and to consider them as merely evidences of intolerance. 3. To follow no fixed rule as to the rate of increase or maximum dose to be reached, but to be guided only by the degree of toxin tolerance of each case as shown by the symptoms and general condition, whether the highest dose attainable be only a small fraction of a milligram or a cubic centimeter or more.

Hemoglobinuric Fever.—W. H. Deaderick reviews the history of hemoglobinuric fever and points out the confusion which has existed in its diagnosis from bilious remittent fever. He does not find any very convincing evidence of quinine being a casual factor, though he says it is probable that the use of this drug may have increased the prevalence in certain localities. The facts that it seems to be decreasing in some regions with the increasing use of quinine and the large number of cases occurring where quinine had not been previously used are to be considered. He thinks that the increase of the disease has been largely influenced by the influx of susceptible whites into regions where the disease is endemic, especially in Africa, where the natives seem to be almost immune. The importation of quinine may have had its influence and the better diagnosis by competent physicians will also have an influence on the apparent frequency.

Renal Lavage.—E. Garceau presents the literature on the subject of renal lavage and reports some personal cases to show the present status of this mode of treatment. The technique is described in detail. He prefers the Kelly cystoscope and says that the operation is simple though some skill is required. The germ usually found is the colon bacillus, but the gonococcus and other germs have also been found. The solution which has given him the most satisfaction is silver nitrate, beginning with a mild one of 1

to 2,000 and gradually increasing the strength. The amount should depend on the condition of the pelvis and kidney. If there is no dilatation, not more than 8 or 10 c.c. should be given at first; the sensations of the patient will be a good guide in this as also in regard to the frequency of the injections. The method is seldom required and care should be taken in selection of cases. As a rule the patient should be under observation for a considerable time before it is undertaken. Acute pyelitis is not suited to this method. Free drainage of the kidney through the ureter must be secured. The most suitable cases are those of simple chronic suppurative pyelitis without obstruction, but most of these will get well anyhow unless the germ is a very virulent one. It may be used to cure an inflammation in a hydronephrotic sac as a preliminary to nephrophexy, but the kidney should be supported meanwhile by an appropriate apparatus. It should never be permitted in severe pyonephrosis with general systemic infection and it is not suitable for tuberculous pyelitis or pyelonephritis. It does little or no good in ureteritis with marked tissue changes in the ureter tending to sclerosis and thickening. The only positive remedy for such chronic cases is nephrectomy. A permanent catheter in the ureter is dangerous, especially in acute infections and with general symptoms. Renal lavage is seldom followed by serious harmful sequels if properly performed in the right sort of case, but further experience is needed to give the method a definite therapeutic standing.

Ureteral Calculus.—C. L. Leonard advocates the expectant treatment of small ureteral calculi, understanding by this method the use of known medical measures under careful medical supervision with frequent analyses of the urine. This treatment is based on the data derived from careful x-ray examinations, together with a study of the symptoms and signs as shown by other methods. He claims that the results from this expectant treatment show that in 50 per cent. of the cases of urinary lithiasis presenting marked symptoms, natural forces are sufficient for the expulsion of the calculus. It is not only rational and justified with the use of the known methods of diagnosis, but should be resorted to rather than the incurring of the dangers of the surgical operations in many cases.

Abdominal Tuberculosis.—D. N. Eisendrath points out that the lesions caused by the tubercle bacillus often simulate acute forms of disease of the abdominal viscera. The structures affected are most commonly the appendix and the peritoneum. His attention was particularly called to these facts by an experience of a near relative who was taken suddenly ill while traveling in Switzerland and operated on by Kocher of Berne, who diagnosed the case as one of tuberculous appendicitis, due to the ingestion of butter containing tubercle bacilli. Eisendrath emphasizes the importance of this source of infection; the cream is apt to be the most intensely infected portion of the milk, and affording no protection against the germicidal action of sunlight, it is an ideal culture medium for the bacillus. He reports several cases of acute tuberculous peritonitis of his own personal observation, and others from various sources in the literature, etc. To 51 cases of tuberculous appendicitis he can add 7, and of the total 16 patients had symptoms resembling in every detail acute appendicitis. His conclusions are the following: 1. A primary tuberculous appendicitis is not so rare an affection as was formerly thought. 2. Such an infection can be followed by secondary involvement of the ileocecal lymph nodes, which is out of all proportion to the pathological changes in the case. 3. In the majority of cases there are evidences of tuberculous foci in the appendix, but secondary lymph caseous nodes may be found without visible macroscopic or microscopic tuberculous changes. 4. Butter, cheese, and milk from tuberculous cows are the chief sources of infection in primary intestinal tuberculosis. 5. In a fair proportion (27 per cent.) of the 59 published cases of tuberculous appendicitis the clinical picture resembled that of an acute nontuberculous appendicitis. No statistics are available to estimate the proportion of cases of tuberculous peritonitis which begin acutely, but the number is larger than is usually thought. 6. Through early diagnosis and radical removal of the tuberculous appendix and infected lymph nodes (so far as practicable) complete and permanent recovery can occur. Some of the cases of ileocecal tuberculosis and of tuberculous peritonitis may thus be avoided through removal of the probable starting point.

Sputum Examinations.—A. T. Laird offers some suggestions in regard to sputum examination for diagnostic purposes. The main points are a more careful use of terms in describing macroscopic appearances, and certain matters to be noted in the microscopic appearance of the sputum. Under "macroscopic appearance" the specimen is described as watery, mucoid, mucopurulent, purulomucoid, purulent, or bloody. If one of the other varieties is simply blood-streaked the fact is noted, but only pure blood is called bloody sputum. In the microscopic examination the presence or absence of tubercle bacilli is noted. Their number is estimated according to the Gaffky scheme and their arrangement is recorded if desired. Under the heading "cells" particular attention is given to squamous epithelial cells and to pus cells (polynuclears). If the former are present in large numbers they are given preference in the statement of cells present, and if the pus cells are numerous they are accorded first. The presence of small round cells, alveolar calls, and, in appropriately stained cells, of eosinophiles, may also be mentioned. Mononuclear cells are rarely in the majority. As regards secondary organisms it is first noted whether they are few or many and then further details may be added. He gives a table showing how in a series of 541 cases there was a natural grouping into four types, the last of which, the mucopurulent with numerous pus cells, he calls the "bronchial type," and says it is desirable to obtain such to determine the presence or not of tubercle bacilli or organisms causing mixed infection. The tubercle bacilli may be occasionally found in the watery or mucoid type or the purulomucoid with predominating squamous cells, which are usually derived from the mouth or throat, but no inferences as to mixed infection should be drawn from the examination of such specimens.

The Lancet, January 16, 1909.

An Efficient Treatment for Pneumonia.—D. Crowley gives the histories of three cases and refers to six others. He gives an initial dose of calomel, followed by doses every four hours of a mixture containing 4 grains of the iodide of potash, 10 grains of citrate of potash, half dram doses of the citrate of ammonia solution, and occasionally little brandy. The dietary in the series of cases consisted of mixed milk and water when it agreed with the patient and when otherwise whey and cold water wherever desired. He also applied linseed poultices over strips of skin which had been previously blistered.

Ileosigmoidostomy for the Relief of Inveterate Constipation.—In one case Mansell Moullin united the lower end of the ileum by direct suture to a convenient portion of the sigmoid flexure, a lateral anastomosis four inches long being made between the two. The ileum was not divided. Recovery was uneventful. On the second day the patient, a woman nearly fifty years old, had a small semisolid movement, the first spontaneous one for some years. Two years later she was still well, though suffering occasionally from flatulency. The author has done the operation in all seven times, all recovering, and claims for it the following advantages: (1) It meets the requirements of the case in the simplest way by enabling the bowel contents to evade that portion of the gut in which they are especially liable to be detained. (2) It is almost devoid of risk. With reasonable care there is a minimum of danger in making a lateral anastomosis between two contiguous portions of bowel when there is no distention, and (3) it does not deprive the patient of any organ, whether this is of service at the time or not. The part of the bowel cut out by the procedure is not entirely deprived of its functions, but it is helped in that an alternative route has been provided for the bowel contents. If the ileum was divided at the end, the continuity of peristalsis would be broken and the condition of stagnation in the first half of the large intestine would be perpetuated rather than relieved.

A Combination of Substances Which Excites Ameboid Movement in Leucocytes by Which Living Can Be Differentiated from Dead Cells.—H. C. Ross has devised a stimulating agar solution, as follows: 3 c.c. of a 2 per cent. solution of agar in water, filtered, neutralized, and sterilized, 1 c.c. Unna's polychrome methyl blue (Grübler), which has been diluted previously with 2 volumes of water, 2 c.c. of a solution containing 4.5 per cent. of sodium citrate, 1.5 per cent. sodium chloride, and 0.225 per cent. sulphate of atropine. Before the atropine is added to the last solution, the latter must be most accurately neutralized to litmus

paper with citric acid. It has been found that the cytoplasm of leucocytes is a jelly which liquefies at death and that the diffusion of stain into it is hastened by heat and alkalies and delayed by neutral salts. Consequently unless there is heat or alkalies are present in certain proportions, the stimulant will not be rapidly absorbed by the cells, while the ameboid movement will either be greatly delayed or will not occur at all. A 5 per cent. solution of bicarbonate of soda is a convenient alkali to use and it must be added to the agar according to the temperature of the room in which the examination takes place. Investigation into the nature of the exciting factor shows that the stain has the most important part. Exaggerated ameboid movements, even at low temperatures, will occur without the alkaloid provided the agar is neutral, in which case the onset of the movement is delayed and not constant. With alkaline sugar the alkaloid is necessary where all the cells show stimulation as described.

British Medical Journal, January 16, 1909.

Body Weight in Relation to Pulmonary Tuberculosis.—F. P. Weber and W. R. Kirkness present the following statistics: In 500 male patients twenty-five years old and upward, all with bacilli, the average height was 5 feet 7 inches. Average weight on admission was 127 pounds 13 ounces. Fifty-three, or 10.6 per cent., weighed more than 147 lbs.; 3, or 0.6 per cent., weighed exactly that, and 444, or 88.8 per cent., weighed less. Average of former ordinary weights was 145 pounds 9 ounces. Two hundred and four of them, 40.8 per cent., used to weigh more than 147 pounds; 16, or 3.2 per cent., weighed exactly that, and 280, or 56 per cent., less. In a series of 100 females twenty-five years old and upward, all with bacilli, the average height was 5 feet 3¾ inches. Average weight on admission was 107 pounds 3 ounces. Eighteen of them weighed more than 119 pounds, 1 exactly that, and 81 under that. Average of former weight was 120 pounds 12 ounces. Fifty-four formerly weighed more than that, 1 just that, and 45 less than that. A third series was also examined of 100 males thirty years old and upward, who presented the physical signs of old pulmonary tuberculosis, but no fever or bacilli. Average height on admission was 5 feet 6¾ inches and average weight 133 pounds 5 ounces. Twenty weighed over 147 pounds, 5 exactly that, and 77 less than that. Average of former ordinary weights was 146 pounds 11 ounces. Forty-eight of them exceeded 147 pounds, 1 was just that, and 51 less. It seems, therefore, that the average weight of this last series on admission and the average of these former ordinary weights were both below the standard, but not so much so as in the first series in which the patients showed signs of active pulmonary tuberculosis, and had had bacilli. This may be taken perhaps to signify a more robust habit of body accompanying their resistance to tuberculosis, a resistance also shown by the relative quiescence of their lung lesions. A tabulated summary of the foregoing figures closes the original paper.

Asthma; Its Cause and Treatment.—According to W. Lloyd there are three causative factors in asthma: (1) The presence of hypersensitive areas in the nasal mucosa or a special sensitiveness of the gastric mucosa. (2) A special irritant of the pulmonary nervous system which constitutes the asthmatic idiosyncrasy with which the patient was born, and (3) the presence of an irritant, e.g. odors, dust, smoke, dietetic errors, etc. Treatment follows according to this classification. In a given paroxysm inquire as to the last meal and remove any obvious exciting cause. If the patient is in a bad atmosphere, remove him. Get him out of bed, bolster him up in an armchair before a cushioned table on which he may rest his elbows and throw himself forward. Ipecac powder will occasionally cut short an attack and permit of a good night. Some patients can get the same relief from pipe tobacco, but all such remedies must be used early. Plain strong hot coffee is one of our surest remedies. Alcohol, cocaine, and chloroform are all serviceable, but the danger of habit formation must not be forgotten. Stramonium smoking and nitre paper fumes are often efficient. The author's experience with the iodide of potash has been disappointing. The food should be nutritious and easily digestible. Asthmatics should dine early, so as to retire on empty stomachs. Intranasal abnormalities must be rectified. For ordinary intranasal irrigation the normal saline are better than the usual antiseptics employed for this purpose.

Causation of Ingrowing Toenail.—G. A. Stephens suggests that a likely cause is the position of the foot during sleep. What usually happens on retiring is that a person first lies on his side, places his feet side by side, but in a short time the upper one slips down onto the bed so as to lie wholly or partially on the bed alongside of the other. If it slides but a short way, then it lies with its weight resting on the toes and it is this constant pressure on the side of the big toe during the sleeping hours that gives rise to the pathological condition. Two simple diagrams explain the author's point. Most persons at some period, he says, have experienced what is popularly known as the "fidgets" when getting into bed in a disturbed and irritable condition. They are restless and do not know what to do with their feet, and if the positions of their feet were noticed it would be seen that the upper foot was twisted about the lower one, with the big toe dug into the bed. The wearing of a toe cap is suggested as a simple means of preventing abnormal pressure on the nail.

The Effective Treatment of Acute and Sub-Acute Rheumatism.—D. B. Lees commends the use of sodium salicylate, but says that its employment has been restricted by fear of cardiac depression and the bad taste of the remedy. It should be used more freely and continued for a longer time. The cardiac changes result from the disease, however, and not from the remedy. The author always finds dilatation of the left ventricle. As long as the evening temperature rises above normal, the disease is still present, and the remedy should be continued. The author says that the addition of bicarbonate of sodium in an amount always double that of the salicylate is a very effectual means of diminishing the unpleasant effects of the latter. The initial dose of the sodium salicylate may be 15 grains for an adult, for a child from 7 to 12 years 10 grains, and below this age 5 grains, the daily totals being 150—100 and 50 grains respectively. With these larger doses the pain rapidly abates and the joint swellings subside. The fever falls and there is little tendency to relapse. The improvement in the heart wall muscle is often most striking. In bad cardiac cases and those associated with pericardial inflammation the author commends the application of ice to the precordium. The lower extremities must be kept warm and any considerable dilatation of the right auricle must be relieved by leeches before the ice is applied. The indications for leeches are an extension of the cardiac dullness in the fourth right intercostal space to two finger breadths, rapid respiration, restlessness, and some cyanosis in the lips and face.

Diabetes Conjugalis.—At a recent meeting of the Berlin Medical Society, Senator discussed the question whether diabetes might be communicated from husband to wife and *vice versa*. He said that some writers, believing that the disease can be so communicated, have proposed the name of "diabetes conjugalis" for this condition. Dr Schmitz of Neuenahr had found 26 married couples among 2320 diabetic patients, being 1.1 per cent. of the total number. The computation ought, however, to be made not by comparing the diabetic couples with the total diabetics, but by comparing the diabetic couples with the diabetic patients who were either married or lived connubially. The proportion of diabetic couples then becomes higher. Senator has observed 516 married couples of whom either the husband or the wife, or both, were diabetic. The latter event happened in 18 instances (*i.e.* 3.5 per cent.), and taking only those couples who had been married from six months to one year the proportion rose to 4.1 per cent. Some of the cases were hereditary, but even 4.1 per cent. was not a proportion sufficiently high to make a communication likely. Some rather striking instances of communication have, however, been recorded, such as that of a washerwoman who had washed the linen of diabetic patients and that of a surgeon who had performed an amputation on a diabetic patient. Some pathologists have produced diabetes in animals by the inoculation of diabetic urine. Experiments of this kind which Senator had made were unsuccessful, but he nevertheless was of opinion that a communication of the disease might happen in certain favorable circumstances. In the discussion Dr. Neumann said that among 108 diabetic patients whom he had observed there was only one married couple presenting this condition. Albre said that he had found diabetes in two married couples, but in one of them the disease was hereditary and in the other it was caused by disease of the pancreas. Ewald stated that in 120 cases he had not seen a single instance of diabetes conjugalis.—*The Lancet*

Book Reviews.

Compendium der Verbandlehre. Von Dr. Eduard Sonnenburg, Geheimer Medizinalrat, ord. Professor honor. an der Universität, und Dr. Richard Mühsam, Oberarzt an der chirurgischen Abteilung des städt. Krankenhauses Moabit in Berlin. Zweite Auflage. Mit 87 Abbildungen im text. Berlin: Verlag von August Hirschwald, 1908.

This is a booklet of ninety pages, and gives the technique of preparing and putting on the ordinary bandages used in surgery. It is well illustrated, and should prove useful to the student; the practising surgeon or physician will hardly need the instructions of the book in improvising a bandage to suit each individual case.

Der Menschliche Körper in Sage, Brauch und Sprichwort. Von Professor Karl Knortz, North Tarrytown, N. Y. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1909.

The author has collected a number of popular sayings, proverbs, and old ditties that refer in one way or another to some part of the human body. We find here the nursery rhyme about the two blackbirds sitting on a hill, an inevitable quotation or two from Shakespeare, and a number of citations from various writers on anthropology. The book may be picked up in a leisure moment, but one would hardly consider it as a serious contribution to scientific literature or attempt the task of reading it from cover to cover.

Action de la Contraction Utérine sur l'oeuf Humain. Phénomènes passifs de la Grossesse et du Travail. Par le Dr. Paul Bouquet, Médecin de la Maternité de Brest, Directeur du Corps Départemental d'Accouchement. Paris: G. Steinheil, Éditeur, 1908.

Dr. Bouquet has taken upon himself the task of tracing the effects of uterine contractions upon the ovum contained in its cavity, from the first day of its attachment to the mucosa to the final stage of labor, when the full term fetus is expelled by uterine action. The book contains a vast amount of information in this special phase of the theory of obstetrics, and is illustrated by a number of pictures showing the condition of the uterus and of the fetus in various stages of pregnancy and labor. The work should be of interest to anyone who is anxious to obtain a complete picture of the dynamics of labor; a number of pages, too, will prove of use to the practical obstetrician in suggesting the means of dealing with such abnormal phenomena as abortion, delayed labor, uterine inertia, etc.

A Synopsis of Surgery. By Ernest W. Hey Groves, M.S., M.D., B.Sc. (Lond.), F.R.C.S. (Eng.), Assistant Surgeon to the Bristol General Hospital; Surgeon to the Cossham Hospital; Senior Demonstrator of Anatomy at the University College, Bristol. New York: William Wood & Company, 1908.

The ordinary manuals of surgery require many months for their perusal, and the larger and more complete works on the subject are almost encyclopedic. One result of this state of affairs is that the student and general practitioner are unable to revise and review their studies in surgery as they should, and as they often would, if it were at all possible. The present volume makes such review both possible and pleasurable. It is not intended to replace the larger works; and, indeed, it would have no value to one who had not carefully studied some standard work; but for review purposes it is admirably adapted, as it gives a synopsis or epitome of the salient facts in surgical practice. In point of size it is about half way between the compend and the textbook. The subject matter is well selected, and by a judicious arrangement of headings, type, and indented margin, ready reference is easy, and the scope of a subject can be seen at a glance. The work is fairly complete as far as it goes, but in another edition sections might well be added on shock and on anesthesia.

A Textbook of Physiology. For Students and Practitioners. By George V. N. Dearborn, A.M. (Harvard), Ph.D., M.D. (Columbia), Professor of Physiology in Tufts College, Medical and Dental Schools, Boston. With 300 engravings and 8 colored plates. Philadelphia and New York: Lea & Febiger, 1908.

This is a new textbook of physiology, written primarily, the author says in his preface, for medical and dental practitioners and students, and it is not only new, but novel. If Dr. Dearborn is as original in his classroom teaching as he is in this work it must be a delight to sit under his instruction. The author is a psychologist as well as a physiologist, and he is insistent in his teaching upon the mutual relation of the mental and somatic processes. He also, as he again notes in the preface, emphasizes "the mechanism of sense-organs, nerves, and muscles as the basis of the individual's efficiency." The most striking feature in the book is the liberal use which the author makes of original diagrams illustrating physiological processes, such as cell-metabolism, digestion, the functions of the lymph-capillaries, thermotaxis, muscular action, urinary secretion, absorption and excretion, etc. For advanced students there are other more complete and detailed treatises, but for the beginner we know of no work more satisfactory than this. Teachers of physiology also will find it full of hints and suggestions whereby they may make their lectures and demonstrations more interesting and instructive, and they will also find useful the Appendix, wherein are found "directions for performing certain fundamental physiological experiments, with brief theoretical notes on the same; a list of topics suitable for essays and conference-discussion; and conversion-tables of various sorts." In fact, any student or teacher of physiology will derive pleasure and profit from this thoroughly original work.

The Bacteriology of the Eye. By Dr. Theodor Axenfeld, Professor of Ophthalmology in the University of Freiburg. Translated by Angus Macnab, B.A., B.Sc., M.B., Ch.B., F.R.C.S.; Chief Clinical Assistant, Royal London Ophthalmic Hospital. With 87 illustrations, some of which are colored, and 3 colored plates. New York: William Wood & Company, 1908.

Macnab's excellent translation of Axenfeld's work makes accessible to English-reading physicians a volume of great merit. The bacteriology of the eye has continued to grow, in importance during the past thirty years until it has reached a stage rendering it imperative that ophthalmologists should be acquainted with its more practical phases, at least. The volume before us presents the subject elaborately and up to date.

Chapter I contains a description of the technique of bacteriological examinations. Chapter II describes the bacterial flora of the normal conjunctiva. Following these are chapters devoted to the consideration of the bacteriology of the various parts of the eye in disease. Chapter IX is occupied with a description of leprosy, tuberculosis, and syphilis as they affect the eye. Chapter X is devoted to the consideration of endogenous infection.

The volume is one of about four hundred pages. It is well printed and appropriately illustrated. The literature of the various subjects treated of has been exhaustively consulted; the bibliography alone is of great value to the student and practitioner of ophthalmology. Those ophthalmologists who read English only are to be congratulated that a volume of such excellence is placed within their reach. Certainly no practitioner of diseases of the eye who desires to be abreast of the times can afford to be without Axenfeld's work.

Diagnosis by the Urine. Or the Practical Examination of the Urine with Special Reference to Diagnosis. By Allard Memminger, M.D., Professor of Chemistry and Hygiene and Clinical Professor of Urinary Diagnosis in the Medical College of the State of South Carolina, etc. Third Edition, Enlarged and Revised. With 27 illustrations. Philadelphia: P. Blakiston's Son & Co., 1908.

This is one of the best known of the smaller works on Uranalysis. It contains chapters on: Physical characteristics of the urine in health; deviations in the physical characteristics of urine in disease; deviations in the normal chemical composition of urine in disease; morbid matters and coloring matters in the urine in disease; urinary sediments; differential diagnosis of chronic Bright's disease; and a *résumé* of the diagnosis of parenchymatous nephritis, interstitial nephritis, pyelitis, and cystitis. The last two chapters are particularly valuable, and the book as a whole can be recommended as a safe guide to students and practitioners.

Obstetric and Gynecologic Nursing. By Edward P. Davis, A.M., M.D.; Professor of Obstetrics in the Jefferson Medical College, Philadelphia; Obstetrician to the Jefferson Hospital; Obstetrician and Gynecologist to the Philadelphia Hospital; Consultant to the Preston Retreat, etc. Third Edition, Thoroughly Revised. Philadelphia and London: W. B. Saunders Company, 1908.

The third edition of this book has been revised and enlarged. It is one of the most useful works on obstetric and gynecologic nursing, and is sure to be appreciated by trained nurses engaged in that class of work. Further, it is a book that the physician can, with safety, recommend to his nurses.

Society Reports.

NEW YORK ACADEMY OF MEDICINE

Stated Meeting, Held December 17, 1908.

DR. JOHN A. WYETH IN THE CHAIR.

This meeting was held under the auspices of the Section on Genito-Urinary Diseases, and was devoted to a symposium on the surgery of ureteral calculi.

The Surgical Anatomy and Pathology of Ureteral Calculus and Its Operative Indications.—Dr. BENJAMIN MERRILL RICKETTS of Cincinnati read this paper, illustrating it with a number of lantern slides. He said that there seemed little more to accomplish in ureteral science other than more perfect means of diagnosis, for the operative technique had been developed to the highest degree. Ureteral anatomy might be classified into normal, pathological, and anomalous, each having distinct macroscopical and microscopical characteristics. The first of these, normal anatomy, was more frequently based upon embryonic development in structure and relation. This class was probably less frequent than the second and third combined. It was to the first that attention was primarily directed in the study of the subject and it was ever uppermost in the mind of the student and therefore better understood. It was taken for granted that all who were especially interested in this subject were thoroughly conversant with its normality. After relating the history of the anatomy of the ureters Dr. Ricketts said that the variations in form of the normal ureter consisted of dilatations, constrictions, isthmuses, reservoirs, spindles, ampullæ, and spirals, each of which might vary in number and dimensions. Ureteral isthmuses were three in number and constant: 1. Proximal ureteral isthmuses were the constrictions located adjacent to the distal renal pole (sometimes called the neck of the ureter). 2. Middle ureteral isthmuses were at the point where the ureter crossed the iliac vessels. 3. Distal ureteral isthmuses were located in the wall of the bladder at the distal end of the ureter (Robinson). Ureteral dilatations were also three: 1. Proximal (calyces and pelvis). 2. Middle (lumbar spindle). 3. Distal (pelvic spindle). They were reservoirs and not due to the obstruction offered to the flow of urine through the ureteral isthmuses or constrictions. Spirality was a common property of the ureter and arose from the Wolffian body. Normally the number of spirals was one and one-half, although as many as five had been observed in one ureter. Anomalous anatomy deviated from the normal structure and relationship in consequence of defective embryonic development such as malformations or malpositions, which might extend to a fatal degree at any time during fetal, infantile, or adult life, or they might be of no consequence in advanced life. Each kidney might have one or more ureters entering the bladder or there might be but one ureter connecting both kidneys with the bladder. Both kidneys might be without any ureter, or numerous ureters might be given off from one or more kidneys each to open independently into the bladder, or one or more openings of one or more ureters might empty into the alimentary canal, the vagina, the uterus, peritoneal cavity, or through the abdominal wall, or there might be an entire absence of ureteral exit. The points of entrance into the bladder might be anywhere above the internal sphincter of the urethra behind or in front of the peritoneum. They might vary as to distance from one another at their points of entrance and might be with or without function to prevent the backward flow of urine, blood, pus, or serum. Their dimensions might be equally varied. They might have a direct or circuitous course to the bladder; they might be straight, spiral, curved, or angular and the circumference might be greater or less than normal. The blood and nerve supply might vary from the normal to any degree, the entire absence of one or both having been observed. The consideration of anomalies had become most important. Under the heading "pathological anatomy" he considered abnormal conditions other than causes due to irregular fetal development. Prolapse might be congenital or acquired, partial or complete, in either sex and at any age. Occlusion represented obstruction due to any cause at any point in any degree, periodic or permanent. Bands, ulcers, cicatrices were all prominent factors in its causation. Calculi formed primarily in the ureter were rare, when they occurred they were composed of phosphatic salts deposited above a stricture or upon an ulcer or foreign body in the ureter. Cysts were infrequently found in the ureter and might be single or multiple, might contain blood, serum, pus, or urine, might be primary or secondary. Rupture was an incident whether due to trauma or disease and there did not seem to be any point of predilection; concretions were the most frequent cause. They were circular or linear in character, seldom involving the entire circumference of the ureter. Fistulæ were due to accident, surgical trauma, or disease. They might be congenital, single, or multiple and might terminate in the alimentary, biliary, or urinary tract, peritoneal cavity, Fallopian tube, uterus, vagina, or upon the external surface of the body. Their most frequent cause was surgical operation for the removal of uterine neoplasms per vaginam. Tuberculosis of the ureter was common as a secondary deposit resulting from tuberculosis of the kidney. Primary tuberculosis was indeed rare. Benign neoplasms were not common but of sufficient frequency to be given due consideration. Ureteritis might be distinguished by several forms or stages. Fournier said that the ureters were chiefly involved in pyelitis. Malignant neoplasms included both sarcoma and carcinoma, either of which might be primary or secondary; carcinoma was the more frequent, and was usually secondary.

Personal Observations Upon Ureteral Calculi.—Dr. ALEXIS V. MOSCHCOWITZ read this paper in which he said that ureteral calculus was a disease that had been added to the domain of surgery only since the discovery of the *x*-ray. Although the number of cases of ureteral calculus had thus been vastly augmented during recent years, they were by no means common incidents and he had been fortunate in seeing an unusual number. One point in the anatomy of this organ was of importance in considering this phase of the subject, namely, that the ureter was narrower at three anatomical points: 1, At or about the junction of the ureter and the pelvis of the kidney; 2, at the vesical end, and 3, at the point where the ureter crossed the common iliac artery. These points of constriction were usually the sites of predilection for the impaction of calculi. In sixteen out of eighteen cases he had found calculus impacted at a point between the vesical end of the ureter and the point where it crossed the common iliac artery, perhaps a trifle nearer to the former. This point of constriction seemed to be due to a dense sharp fascial band which passed horizontally inward from the lateral pelvic wall to the median line. He had found it necessary always to divide this band of fascia in order to mobilize the lowermost segment of the ureter. He said that, in his opinion, the presence of microscopic blood in the urine was a very important symptom of either renal or ureteral quiescent calculus. If the calculus was migrating there were all the classical symptoms of renal colic with the hematuria greatly augmented. The symptoms of quiescent and migratory calculus usually alternated, the periods of remission having a tendency to become shorter and shorter. A calculus in the ureter might give rise to symptoms referable to the bladder, but only when the calculus was situated near the vesical end of the ureter. As an aid in locating the site of the calculus symptoms were very misleading, the tenderness usually extended to the entire region of the ureter. Cystoscopic inspection of the bladder

was also of comparative limited value in diagnosis. The cystoscopic passing of the ureteral catheter afforded better knowledge than the previous two methods of physical examination. Occasionally a ureteral catheter would pass readily even if a calculus was present. The most important and pathognomonic method of examination was the *x*-ray. The *x*-ray examination was an absolute necessity because: 1. It indicated the presence or absence of a calculus. 2. It showed the situation of the calculus. 3. It showed the number of calculi; this was important because it occasionally happened that there were two or more calculi in the ureter. 4. It showed the presence or absence of an associated renal calculus. If doubt existed as to whether a given shadow proceeded from the ureter or not, additional evidence could be obtained by passing a styletted ureteral catheter to the point of obstruction and again subjecting the patient to the *x*-ray. If the shadow was derived from something extraneous to the ureter the shadow of the catheter would be found to lie at one side or the other of it. No calculus should be allowed to remain indefinitely in the ureter. The matter to decide was at what period in the course of the disease surgical interference became necessary. Personally he said that he did not advise operation as soon as the diagnosis was made, but observation of the case in order to allow natural forces full scope in the propulsion of the concrement. He related a number of cases to demonstrate that this was the better course. It was surprising to see what nature could do in the propulsion and expulsion of ureteral concrements. The one drug indicated in attacks of renal colic was morphine. He thought he had seen favorable results from hot applications. Calculous anuria, whether reflex or caused by a unilateral impacted calculus, was an indication for immediate operation. So-called reflex anuria due to a calculus in one kidney was an exceedingly rare phenomenon. He had formerly advocated and practised as an emergency measure in these cases the operation of bilateral nephrostomy, but with the present facilities for the taking of an *x*-ray picture in every large hospital he now favored the immediate operation of ureterolithotomy, single or bilateral. He had operated in and observed four cases of anuria and he related one case due to calculous ureteral obstruction. The method of procedure for the removal of ureteral calculus depended primarily upon the exact point where the calculus was located. The various precedures possible suggested themselves almost infinitely. He outlined the usual methods in the briefest manner, citing one case in which he had dislodged the calculus by manipulations with the ureteral catheter. He believed that the possibility of peritoneal infection by extravasated urine almost forced the adoption of the extraperitoneal method, though this route was a trifle more difficult than the intraperitoneal method. In regard to drainage he said that he had abandoned the cigarette drain for a rubber tube drain through which a strip of gauze had been pulled. This was eminently successful until recently in a case of bilateral ureteral calculus the tubes caused a large slough in the walls of both external iliac arteries, with secondary hemorrhage necessitating simultaneous ligation. Since this accident he had had recourse to the cigarette drain. He gave a history of the cases in which he had operated and said that in regard to prognosis he did not believe that he would meet with much opposition when he stated that obstruction of the ureter by calculi for any length of time would sooner or later be followed by the infection of either the pelvis or parenchyma of the kidney. On the other hand the removal of such calculi was followed by almost ideal results. The mortality in experienced hands was practically nil; the operation was comparatively easy; the period of convalescence was short, not more than two weeks as a rule; the patient was immediately relieved of all distressing symptoms, and full return of health was probable if the function of the kidney had not been seriously interfered with by the disease; the danger of subsequent hernia was very slight and did not merit serious consideration.

The Operative Technique of Calculi Impacted in the Lower End of the Ureter.—Dr. C. L. Gibson described the method he had pursued (with illustrations), and reported two cases. The incision he used was a modified Stimson-Pfannensteil, the patient having been placed in the Trendelenburg position. By means of this incision the ureter was more exposed, the calculus more readily removed, and the ureter could be more thoroughly stitched. The incision should be made with great delicacy in order to keep out of the peritoneal cavity. The incision was a little more extensive than the one ordinarily used.

Cystoscopic Aid in the Diagnosis and Treatment of Ureteral Calculus.—Dr. A. T. Osgood said that there were cases in which it was unnecessary to resort to the introduction of intravesical instruments: in those cases in which the history, physical signs, urine examination, and positive radiographs pointed in a classical way to ureteral calculus of such size and shape that experience taught might pass by physiological methods into the bladder and be expelled from that viscus, the patients should not be subjected to the discomfort and dangers of instrumental manipulation. There were two positive means for determining the position of a calculus, the radiograph and ureteral examination by the cystoscope with the ureteral bougie or catheter. The *x*-ray would fail in the case of pure acid or pure urate calculi. The cystoscope should be used (1) to establish a diagnosis of ureteral calculus and to determine its situation; (2) in all cases in which operative relief was in question, because no diagnosis was complete and the preoperative examination of every case was faulty if the condition of the other kidney was not known when one ureter or kidney was to be dealt with surgically; (3) it should be used for therapeutic purposes. The cystoscope might show the calculus fixed in the ureter mouth projecting into the bladder and so make possible its removal. A calculus in the intramural portion of the ureter presented the appearance of a rounded elevation within the bladder, which might be the seat of hyperemia or edema of the overlying mucous membrane. Congestion, edema, submucous extravasation, or prolapse of the ureteral mucous membrane in the bladder was readily visible through the cystoscope; the picture was not pathognomonic of an obstructing body within the ureter, but strongly suggested such a possibility. Complete occlusion of a ureter by a stone occurred at times and then with the cystoscope no fluid was seen ejected from this ureter even after hypodermic injection of indigo-carmine. The ureteral catheter was used for diagnosis in three ways: (1) As a probe or bougie, (2) as an evacuating tube, and (3) as the sheath for a stylette. In the great majority of cases of ureteral calculus, the stone presented no appreciable obstruction to the passage of a catheter past it. In some cases the catheter impinged directly upon the calculus, but a little manipulation permitted its passage beside and beyond it. The phonendophore or auscultatory bougie for the ureter was one of the most valuable of instruments for the diagnosis of ureteral calculi. This instrument was not, however, infallible. The wax-tipped catheter method devised by Dr. Howard Kelly was one of the best means for obtaining evidence of calculus when employed through an open tube (like a urethroscope), but it was not adaptable to cystoscopes because of the danger of scratching the wax by contact with parts of the instrument. Having passed into a ureter containing a calculus or beyond this partial obstruction, the catheter might withdraw the secretion of the kidney and in this fluid might be found the morphological elements denoting hemorrhage or infection, or both. The *x*-ray was a most valuable guide in the diagnosis of ureteral calculi, especially in conjunction with a demon-

stration of the course of the ureter by means of the shadow of a stylette which lay in the ureter. Dr. Osgood closed his paper with a few lantern slides.

X-Ray Aid in the Diagnosis of Ureteral Calculi.—Dr. L. Jaches said that before the advent of the Roentgen rays a diagnosis of ureteral calculus could not be made with any degree of positiveness. The Roentgen rays informed the surgeon of the number of stones present, whether unilateral or bilateral, whether in one place or in more, whether in the ureter alone or also in the kidney of the same or opposite side. They gave the surgeon an idea of the shape and size of these stones. The percentage of error was to-day very small. Pure uric acid calculi might escape detection, but fortunately they were rare, the majority being made up of the combination of the various ingredients. Experience in the interpretation of radiographs would enable one to rule out most of the non-calculous shadows. The cleaner the intestinal tract, the less chance for doubt, and the less occasion for unnecessary exposure of the patient. The *x*-rays were but one more means that made the diagnosis of ureteral calculus possible, but it should be born in mind that the radiographer was as much interested in the clinical aspects of the case as the surgeon who consulted him. Only when both worked hand in hand were the best results obtainable. Dr. Jaches closed his paper with a few lantern slides.

Dr. Howard Lilienthal called attention to a point of importance, the similarity of the symptoms of appendicitis and those of ureteral stone, and said that in spite of all the diagnostic aids a great many appendices were removed when the symptoms complained of were not caused by conditions in the appendix but by the presence of ureteral stone. It was now his custom to have the urine examined carefully in every case of relapsing appendicitis to learn if blood or other cells were present. If blood cells were found, an *x*-ray was invariably taken. It was absolutely impossible without the use of the *x*-ray to make a diagnosis between appendicitis and impacted ureteral stone.

Dr. George Woolsey spoke of experience he had had with ureteral calculi and of the failure of the *x*-ray in aiding in diagnosing such cases.

Stated Meeting, Held January 7, 1909

The President, Dr. John A. Wyeth, in the Chair.

A Synopsis of Two Years' Work of the Academy.—Dr. John A. Wyeth, who had been reelected President, made a report of the scientific work of the Academy for the last two years. He also made a most gratifying statement as to the condition of the Academy, both financially and in regard to membership. The waiting list of the Academy had grown to such an extent that it became necessary to amend the Constitution, raising the limit of membership from 1,000 to 1,200. The number of Fellows on the roll December 29, 1908, was 1,199.

At the close of his address the President said: "I deem it my duty to refer to an incident which must be deplored by every one who holds that the Academy should represent the highest ideals in medicine, that it should not permit its privileges to be prostituted to commercialism, or misleading and untruthful reports of its transactions to be scattered far and wide in the public press. In commenting upon this incident, an editorial writer in the *New York Medical Journal*, in deprecating the laxity shown by medical societies in allowing undesirable papers to be presented at their meetings, criticised the New York Academy of Medicine when it gave an individual the privilege of exploiting a matter connected with the treatment of tabes dorsalis in such a way as to bring him the tremendous advantage of newspaper laudation. So palpable was the blunder, the writer said, that the New York Neurological Society very promptly signified its disapproval. With a knowledge of the facts, it would be difficult to justify this criticism, and the facts could easily have been obtained from the Council of the Academy. The paper in question was subjected to the same careful scrutiny which is given all the material offered to the Academy. It is held that every Fellow is entitled to the privilege of submitting his views upon any topic in medical science, provided that, after examination, they shall be deemed of sufficient importance to justify their presentation from the platform or through the discussion.

"In this particular instance the subject was 'Locomotor Ataxia,' concerning which it is possible that we have not yet reached the Ultima Thule of knowledge. On May 16th, 1907, a member of the Academy presented a short paper entitled 'Locomotor Ataxia: A New Theory as to Its Cause.' The theory advanced received respectful attention and excited, so far as I am able to inform myself, no comment or criticism. A year and five months later, the same Fellow requested the privilege of reporting to the Academy the results obtained by him in the treatment of a series of cases. Before permitting the paper to be listed, by consultation with a member of the Academy and another physician not a member, both gentlemen of high standing and experience in Neurology, I satisfied myself that the paper was of sufficient importance to justify its presentation. On October 1, 1908, under the title of 'Locomotor Ataxia: A Report of Thirty Cases,' it was read and discussed by several members prominent in neurology and general medicine. On the day following and thereafter, the newspapers of this country and abroad printed despatches from the Associated and the United Press, two organizations engaged in the widespread distribution of news, which were sensational, distorted, exaggerated, and in a large measure untruthful accounts of the proceedings of the Academy, to which was added the crowning falsehood that the claims advanced by the reader were endorsed by Dr. John A. Wyeth, President of the New York Academy of Medicine. Of the source of this misinformation to the public press, I have not the slightest idea. I am not willing to believe that any member of the Academy would consent to, let alone take part in, a transaction so undignified and unprofessional."

The Pollution of Our Tidal Harbors.—Dr. George A. Soper, President of the Metropolitan Sewerage Commission, said that the discharge of sewage into tidal harbors frequently produced extensive public nuisances and had sometimes led to disease. There were many cities in Europe and some in America which had already constructed works for the sanitary protection of the tidal waters upon which they were situated. Many more harbors needed protection. Harbor waters had a large capacity for harmlessly and inoffensively disposing of sewage, provided there was a considerable range of tide and the resulting tidal currents were favorable to the mechanical transportation of the sewage to sea or its intermixture with a large proportion of the water. Although the capacity of harbors for sewage was great, this capacity was often overtaxed. It was well within the range of engineering possibility to purify sewage, but the cost of collecting and purifying large volumes of sewage was great. It was a hopeless undertaking to attempt to save the manurial ingredients of sewage with the object of securing a profit. The aim in purifying sewage should be to dispose of this offensive and dangerous material at the least cost and with the least inconvenience and danger to health. The dangerous possibilities of sewage depended upon the microbes of disease which it contained. The reduction of sewage to a harmless mineral form was essentially a process of combustion, whether that process took place after or before putrefaction had set in. Little was known concerning

the fate of bacteria which were discharged into tidal waters with sewage, but such evidence as existed led to the belief that they were, for the most part, rapidly destroyed. The greatest danger existed near sewage outfalls and while the sewage was fresh. In view of the large number of excessively polluted rivers and harbors which existed, it was surprising that so little sickness was known to be produced from them. It was probable, however, that more sickness was so produced than the statistics indicated. One of the chief objections to a polluted harbor lay in the offenses to the sense of sight and smell which polluted waters presented. The offensive visible conditions might be largely prevented by comparatively simple methods of sewage purification. Offenses to the sense of smell must be avoided by purifying the sewage artificially or utilizing the transporting and assimilative power of the harbor waters. The greatest danger to health from polluted harbors lay through the medium of shellfish. Bathing in polluted waters was also dangerous. Steps were being taken to improve the sanitary conditions under which shellfish were produced; this danger was gradually being eliminated, but much remained to be done. The arousing of public interest to a point of having a system of sanitary protection formulated and carried out had generally depended, Dr. Soper said, upon the action of large commercial bodies.

AMERICAN ROENTGEN RAY SOCIETY.

Ninth Annual Meeting, Held in New York, December 28, 29, and 30, 1908.

Dr. Eugene W. Caldwell of New York, President.

Officers Elected.—The following officers were elected to serve for the ensuing year: *President,* Dr. George W. Johnston, Pittsburg; *Vice-Presidents,* Drs. Wm. Allen Pusey, Chicago; Sidney Lange, Cincinnati, Ohio; A. W. Crane, Kalamazoo, Mich.; W. S. Newcomet, Philadelphia, and H. W. Van Allen, Springfield, Mass; *Secretary,* Dr. Percy Brown, Boston, Mass.; *Treasurer,* Dr. Chas. F. Bowen, Columbus, Ohio; *Executive Committee,* Drs. F. H. Baetjer, Baltimore; Henry K. Pancoast, Philadelphia, and Alfred T. Osgood, New York. Detroit was selected as the place for holding the next meeting.

Value of Roentgenographic Examinations. — Dr. Geo. H. Stover, Denver, Colo., said that the first and greatest value of the roentgenographic examination lay in the fact that it gave information regarding conditions existing in the sick or injured individual, which, in some instances, could not be obtained in any other way, and that it amplified or confirmed evidence obtained by physical examination. Failure to make use of this means of diagnosis in known or suspected cases of fracture, dislocation, diseases of bones, and in the search for and localization of foreign bodies constituted negligence. It was not a dangerous agent in the hands of the expert. The roentgenologist was an expert, and he should not furnish the patient or his physician with a picture or print. The plate should be studied carefully, if possible with the patient's physician, and an opinion given. The possession of a plate or print by the patient might prove unfortunate for the physician and for the patient, who was not in a position to read correctly what the plate showed. Neither ought skiagrams be exhibited to a jury. The members of the jury were not capable of reading a skiagram, and they might give more weight to it as evidence than it deserved.

Dr. A. L. Gray, Richmond, Va., agreed with the author that prints should never be made either for the patient or his physician. The written opinion of the radiographer ought to be sufficient, and often such a course saved the physician much annoyance and trouble, as when he had failed to recognize an obscure case of fracture.

Dr. M. H. Kassabian, Philadelphia, believed that the skiagram was a most valuable court record because it was tangible evidence.

Roentgen Diagnosis of Osteitis Fibrosa.—Dr. S. Cummings, Toronto, Can., said that this disease, which was first described by von Recklinghausen, was essentially a disease of the bone marrow, which might be localized in a single bone or which might invade the entire bony skeleton. The normal bone marrow was replaced by a fibrous or lymphoid material, and the bone was replaced by osteoid tissue with the formation of cavities or cysts. The continuity of the bone was not interrupted unless a fracture had occurred. Prior to the introduction of the Roentgen ray as a diagnostic agent, the disease was rarely recognized, and now it was believed that many cases of so-called fragilitis ossium were really cases of osteitis fibrosa. Furthermore, it was probable that many cases of sarcoma in which the surgeon simply scraped out the bone, and a recurrence did not result, were also cases of osteitis fibrosa.

Radiographic Examination of the Gastrointestinal Tract in Gastroenteroptosis.—Dr. Henry K. Pancoast, Philadelphia, said that in order that this work prove valuable, it was essential that the radiographer should be thoroughly familiar with the normal anatomical relations of the stomach and other abdominal viscera, their normal skiagraphic appearances, and the range of variation within normal limits. Nearly all of the abnormal conditions of the stomach which could be studied to advantage by means of the Roentgen ray were in some way related to gastroptosis. The skiagraph frequently indicated the anatomical defects most in need of correction, or those whose correction was most likely to be followed by favorable results, and in suggesting the most appropriate means to employ. The position of the liver, colon, and gastrohepatic ligament must also be determined. It was impossible to radiograph adhesions, but their presence and location might be indirectly suggested in many instances, particularly when they involved the colon. The indications for operation were especially marked dilatation, retention of food, a mechanical kink, and a relaxed gastrohepatic ligament.

Roentgenographic Study of Motion in Viscera.—Dr. Chas. Lester Leonard, Philadelphia, said that, owing to the rapid exposures which could now be made, it was possible to study in detail the result of motion in the viscera, and dilatations and hypertrophies of the left auricle and right ventricle could thus be detected which escaped all other means of diagnosis. The same was true of small aneurysms and dilatations of the aorta, differentiating them from mediastinal tumors. The normal cycle of motion of the viscera, and their abnormal variations could be studied. A better knowledge of the movements of the stomach would aid in differentiating between sthenic and asthenic mobility, and thus determine more accurately the causes of gastric motor insufficiency. The movements of the viscera were not so rapid that they necessitated very short exposures.

Roentgen Rays in the Diagnosis of Gastric Carcinoma.—Dr. George E. Pfahler, Philadelphia, advised resort to both roentgenoscopy and roentgenography in the diagnosis of gastric carcinoma. A thorough clinical study of the case should first be made. The author had examined twenty-nine cases in which evidence of carcinoma was clearly demonstrable, and in most of which the diagnosis was confirmed by operation, autopsy, or the subsequent course of the case. While in most of the cases the disease was well advanced and the clinical evidence of carcinoma was fairly strong, in the majority of the cases the tumor was not definitely or at all palpable. In all of the cases the ray located definitely the tumor and indicated its extent. The evidences of carcinoma of the

stomach might usually be classed under changes in the course of the food through the stomach, changes in outline, position, peristaltic movements, or mobility of the organ. Hour-glass contraction of the stomach was usually evidence of advanced disease; localized or general diminution of the stomach shadow was another sign; indentations of the stomach wall and interruption of the peristaltic wave at a certain point on the greater or lesser curvature also afforded strong evidence. Rapid or deferred evacuation of the stomach contents was another sign of value.

Roentgen Ray in Gastric Ulcer.—Dr. A. W. Crane, Kalamazoo, Mich., stated that the points to be noted in making a Roentgen diagnosis of gastric ulcer were the size, form, and position of the stomach and the location of the "pain marker." The latter was a lead letter P, which was fastened to the skin with adhesive plaster over the seat of the pain, thus marking definitely on the plate the exact location of the pain, whether in the stomach, the duodenum, the pancreas, or some other organ. The globular and contracted forms of stomach were distinctive of ulcer or scar tissue from an ulcer at or near the pylorus, causing partial or complete stenosis. However, a deformed gastric outline might be caused by pressure, a local contraction of the stomach wall, adhesions, or tumor; therefore, the roentgenologist must be thoroughly familiar with the normal and the pathological variations, not only of ulcer of the stomach, but of all other diseases of that viscus.

Treatment of Sinuses with Bismuth, Roentgen Ray, and Electricity.—Dr. Arthur Holding, Albany, had for many years employed a method in the exploration and treatment of old sinuses that had yielded very satisfactory results. He first injected into the sinus an aseptic suspension of subnitrate of bismuth, one part, in vaseline, two parts, using a glass syringe of large capacity. Then a radiograph was made which showed the exact size and ramifications of the tract. Next a copper wire electrode was fashioned so that it could be inserted to the bottom of the sinus. This electrode was fastened to the positive pole of a galvanic current and the sinus was treated as often as was necessary in order to remove scar tissue, stimulate granulations, and render the tract thoroughly aseptic. When the discharge was controlled, the sinus was injected with a mixture of equal parts of bismuth and iodoform to two parts of vaseline and soft paraffin. The sinus closed promptly after this injection.

Dr. Chas. Lester Leonard, Philadelphia, said that the injection of the sinus with iodoform was sufficient for radiographic purposes, inasmuch as the iodoform was metallic and gave sufficient obstruction to the ray to show the tract of the sinus.

Dr. Geo. C. Johnston, Pittsburg, said that in the Children's Hospital in Pittsburg the bismuth injection of sinuses had worked wonders, curing many old and obstinate cases. The therapeutic effect of bismuth seemed to be greater than that of iodoform.

Dr. H. W. Van Allen, Springfield, Mass., failed to see the necessity for the use of the copper wire, the injection of the tract with bismuth being sufficient to effect a cure.

Dr. H. W. Dachtler, Toledo, Ohio, and Dr. S. Cummings, Toronto, reported cases of poisoning from the use of bismuth subnitrate in these cases. The latter thought it better to use the carbonate than the subnitrate.

Pathology and Surgical Treatment of Chronic Roentgen Ray Dermatitis.—Dr. Charles Allen Porter, Boston, claimed that there was always a time when the chronic Roentgen ray lesions could be successfully eradicated by minor operations, but that neglect had led to the necessity for major operations, in spite of which metastases and death occasionally occurred. No agent was so potent in the production of multiple carcinomata in man as the Roentgen ray. The most important changes were the rarefaction beneath the epidermis with total loss of the papillæ and a teleangiectatic condition of the blood-vessels, disappearance of the glands, obliteration of the arteries, and great increase in the connective tissue. The epidermis was thin and atrophic, with foci of epithelial proliferation, in some instances giving rise to papillary downgrowths, with keratoses, and in others there was an invasive type of new growth. Apparently the repeated exposures produced chronic changes in which the normal reparative power of the tissues was lost. There was no constant change in the nerve trunks; in a few instances degenerated trunks had been found in which the nerve fibers were replaced by connective tissue. The nerves were compressed by the dense cicatricial tissue about them, and this might explain the extreme pain so characteristic in many of these cases. Of forty-four cases recorded in the literature, eleven of which occurred in the author's practice, six were of the ulcerative type, four were beginning epitheliomas, and thirty-four were undoubted carcinomas; there were eight deaths. There was always a latent period, usually extending over years, and either keratoses or ulceration always preceded the cancer. The only treatment which would prevent trouble was early removal by caustics or the knife of all suspicious lesions. When occurring on the back of the hand, these lesions might be excised and the wound sutured, or they might be destroyed by liquid air or by carbon dioxide snow. When the keratoses or ulcerations occurred on the dorsal aspect of the fingers, and especially where the skin was dense, the author advocated excision and skin grafting. If the primary grafts did not take, owing to inadequate blood supply, the surface might be grafted again later when granulation tissue had formed. Healing by cicatrization sometimes occurred, but owing to the thinness of the epidermis and the liability to subsequent injuries, skin grafting was preferable. The thicker the grafts, the better the ultimate result, but moderately thin grafts took better than thick ones. Hemorrhage should be controlled before the application of the grafts, and pressure must be maintained for twenty-four hours.

Dr. William Allen Pusey, Chicago, urged a distinction between the acute and the chronic lesions. The former should be treated like any other burn; in the latter, operation was most effective in producing speedy cure. The chronic lesions resembled senile keratoses and were the result of intense exposures extending over a short period of time. The condition, he said, was analogous to that seen in xeroderma pigmentosum, where the skin was extremely sensitive to actinic rays. First there was the atrophy of the skin, then the keratoses followed, and finally epithelioma. The lesions should be looked after early when the surrounding tissues were fairly healthy. Where the lesions were distinctly epithelomatous, the only satisfactory treatment was excision, and skin grafting if necessary. He had treated one or two such epitheliomas with the ray and had found them as susceptible to such treatment as ordinary epitheliomas, but did not recommend that as a method of treatment; nor did he recommend the use of carbon dioxide snow, except when the epithelioma was no larger than a wheat grain. However, liquid air or carbon dioxide snow were very convenient for destroying senile keratoses. They should be destroyed as rapidly as they developed because the beginning lesions might be keratoses or precancerous.

Dr. Charles Lester Leonard, Philadelphia, thought that the great difficulty was the determination when to operate, when nature would no longer do her share in producing a cure, when the individual was no longer capable of recovering his physiological balance and when surgical intervention was necessary. He had yet to find in the list of those who died as the result of chronic Roentgen dermatitis one who had not been subjected to repeated operations.

Roentgen Ray in the Diagnosis of Urinary Calculi.—Dr. Charles Eastmond, Brooklyn, studied eighty cases and found that urinary calculi were present in only twenty-four per cent. of the patients who presented classical symptoms, and in only fourteen per cent. were they present in the suspected region, while in forty-one per cent. of the cases with vague and uncharacteristic symptoms calculi were demonstrated; therefore, he was convinced that the clinical history alone was not sufficient for diagnosis, and that not only should the urine be examined carefully, but a careful radiographic examination should be made in every case of suspected urinary calculus.

Dr. Charles Lester Leonard, Philadelphia, said that no surgeon would operate in a suspected case of renal or ureteral calculus without calling the Roentgen ray to his aid. He was the first to claim the possibility of making a negative diagnosis in these cases. He had only two per cent. of error in the negative diagnosis and three per cent. in the positive. In 32 cases of ureteral calculus in which he made the diagnosis the patients passed the stone under expectant treatment; in only five or six cases was it necessary to remove the stone by operation because of the onset of obstructive symptoms.

Dr. F. H. Baetjer, Baltimore, cited one case in which the radiograph showed three shadows, apparently ureteral stones, which at the operation proved to be one stone and two cicatrices. He also saw one case in which the stone was found on the side opposite to where the symptoms located the stone. For ureteral catheterization he used a catheter made of canvas which was shellaced. In one case the radiogram showed a stone the size of the end of the little finger just above the entrance of the ureter into the bladder. At the operation no stone was found, but later, at a subsequent operation for some pelvic trouble, a small calcified myoma was found in the exact spot where the radiograph showed a stone. He has examined between seven and eight hundred persons for kidney stone. Of this number sixty per cent. were sent to him with a definite diagnosis of stone; the remaining forty per cent. were sent with the idea of ruling out the possibility of stone. Among the sixty per cent. stone was found in only forty per cent., and yet all the cases in this class gave a typical clinical history.

Dr. A. L. Gray, Richmond, advised making a plate to include the structures as high up as the eleventh rib. He stated that with accurate technique it ought to be possible to show a stone, if present, even when made of phosphatic deposits.

Dr. George E. Pfahler, Philadelphia, pointed out that a source of error was change in position of the stone, as when the operation was deferred for some time. In one case he found a stone in the kidney, and when the patient was operated on two months later no stone was found. It was found subsequently in the ureter. Another source of error was in mistaking a mole on the skin for stone.

Dr. Lewis Gregory Cole, New York, pointed out that a wax-tipped catheter might pass a stone or any other obstruction without being scratched. He cited several cases in point. He also had four cases where the stone was on the side opposite to that indicated by the symptoms. He, too, had had moles make a confusing shadow.

Dr. Eugene W. Caldwell, New York, cited several instances in which stone was present, and yet the radiograph failed to show it.

Dr. Vernon J. Willey, Ann Arbor, Mich., thought that often plates of different density would show a calculus, so that more than one plate should be made in every case if no stone was shown and yet the symptoms indicated stone.

Present Status of Roentgen Therapy.—Dr. George C. Johnston, Pittsburg, said that the physiological action of the Roentgen ray was as follows: It possessed analgesic and antipruritic properties; it stimulated metabolism; overdosage resulted in overstimulation and tissue death, the more highly specialized structures and the less resistant diseased tissues being the first to suffer; it inhibited secretory and glandular activity; it seemed to possess a germicidal effect, due to tissue proliferation and increased leucocytosis. Success or failure in radiotherapy depended on the ability of the operator to produce a proper quality of radiation, to administer it in such qualities as to constitute a correct dose, and an acquaintance with the disease process; the operator must be thoroughly familiar with his apparatus. Experience in radiography was the best training for radiotherapeutic work. The results of treatment in acne, especially the pustular form, were usually good. Large doses should be given so as to produce a first degree dermatitis. In acute eczema, the itching was checked promptly and excellent results were often obtained in cases that had resisted energetic treatment by other means. In the various diseases of the skin that were characterized by glandular hyperactivity, the inhibitory action of the ray was extremely beneficial. In lupus vulgaris, the result of Roentgen therapy was most striking, but the treatment must be persisted in for a sufficiently long period of time. Cases of lupus that did not yield to this treatment were usually cases of syphilis, and would yield to specific treatment. In sycosis, favus, and tænia tonsurans a quick and painless depilation might be effected with the ray, after which the ordinary measures employed would prove successful. In hypertrichosis its use was not satisfactory, because in order to produce permanent depilation more raying must be done than was consistent with safety. In psoriasis, limited in extent and essentially chronic, the *x*-ray was the treatment of choice. The same was true of small rodent ulcers. Epitheliomas on or about the eyelids could be better treated by the *x*-ray than by any other method. They must be attacked vigorously and a marked reaction produced early. No local application of any kind was permissible. Crusts and scabs must be removed before each treatment. In exophthalmic goiter, especially when associated with hyperthyroidism, excellent results had been obtained. The nervous unrest disappeared promptly, the exophthalmus was lessened, the tachycardia declined, and the dyspnea disappeared. He had seen no relapses in these cases. The results obtained in the treatment of tuberculous glands compared favorably with those obtained by surgical treatment. In leukemia and Hodgkins' disease only temporary improvement was obtained. In the treatment of carcinomas, Roentgen therapy should be combined with surgery, raying both before and after operation. The treatment of sarcoma resolved itself into surgical measures, the use of Coley's toxins, and the Roentgen ray.

Dr. William Allen Pusey, Chicago, had had an experience corresponding with Dr. Johnston's. He said that if he had cervical gland tuberculosis he would be treated with the Roentgen ray rather than by operation. In sarcoma, he had had many very remarkable temporary results. In one case of large sarcoma of the chest, the tumor literally melted away and did not recur for about two years. Where nothing else could be done in these cases of sarcoma, much comfort could be given the patient by radiotherapy, although no encouragement as to permanent results could be given. He had not found any kind of an epithelioma that would not yield to this treatment.

Large Tumor of Mediastinum Treated Successfully by the Roentgen Ray.—Dr. W. S. Lawrence, Memphis, Tenn., said that the tumor in this case, a black, nonpulsating mass about six inches in diameter, occupied the entire upper central part of the thorax, the chest wall bulging. The patient was rapidly losing strength, suffered considerable pain, and had a very distressing cough. Several prominent surgeons diagnosed the case as one of dermoid cyst and sarcoma of the pleura re-

spectively. The first evidence of the trouble was noticed in the summer of 1906, consisting of bulging of the chest wall. Late in October, 1907, Roentgen ray exposures were begun. About twenty-eight treatments were given extending over a period of two months and the improvement was prompt and continuous. The mass disappeared almost entirely and the patient was now comfortable and able to attend to a large mercantile business.

Value of the Roentgen Ray in Mediastinal Tumors.—Dr. Russell H. Boggs, Pittsburg, had found the ray exceedingly useful in the differential diagnosis of tumors of the mediastinum, especially as between aneurysm and solid tumors. He reported two cases in which the radiograph disagreed with the clinical diagnosis and was proved to be correct. In a third case the Roentgen ray diagnosis of enlarged thymus was confirmed by operation.

Examination of Lungs by the Roentgen Rays.—Dr. Henry Hulst, Grand Rapids, Mich., showed that a radiographic diagnosis of lung tuberculosis could be made before the physical signs were sufficiently well developed to make this possible. He was of the opinion that tuberculosis began usually in the bronchial lymph nodes at the root of the lungs rather than in the apices, as was generally believed.

The Roentgenologist and His Specialty.—Dr. Percy Brown, Boston, pointed out that whereas in the early history of radiographic work the photographer, the chemist, and the dermatologist did this work, such great progress had been made in this field that it was necessary for the roentgenologist to be all three, besides being an able diagnostician, a first-class electrician, and, above all, thoroughly capable of reading a plate intelligently. In other words, the roentgenologist was as much a specialist as the surgeon, the gynecologist, or the internist, embodying in his specialty a knowledge of all other specialties and of many other professions and vocations.

Pathological Society of Philadelphia.

At a stated meeting held December 10 Dr. H. B. Allyn exhibited a specimen of "Aneurysm of the Abdominal Aorta." Dr. D. J. Karsner exhibited specimens of "Hyalo capsulitis of Liver and Spleen." Drs. Jos. Sailer, C. B. Farr, and J. C. Gittings presented a number of specimens of cardiac abnormalities, including vegetative endocarditis, multiple valvular disease, aneurysm of the heart, and splenic infarction. Drs. Krumbhaar, John Funke, and Allen J. Smith exhibited specimens of "Hypernephroma." Drs. George B. Foster and Charles H. Gerhard presented a communication entitled "The Simultaneous Occurrence of Hypernephroma and Carcinoma. A Report of Two Cases." In the first case the patient presented the clinical phenomena of carcinoma of the stomach, the neoplasm of the kidney discovered after death not being suspected during life. Dr. Randle C. Rosenberger presented a communication entitled "Bacteriologic Studies of the Blood in Tuberculosis." He was able to show from examinations in fifty cases that tubercle bacilli are present in the circulating blood in all cases of tuberculosis, even at an early stage of the disease. The technic is simple, 5 c. c. of blood being withdrawn and sedimented for twenty-four hours in sodium-citrate solution, the sediment spread on slides, dried over heat, laked and stained. These observations are a sequel to earlier ones demonstrating the presence of tubercle bacilli in the stools of patients suffering from tuberculosis. Dr. F. Creighton Wellman by invitation presented a communication on "Insects in Their Relation to the Tropical Diseases of Man." He dwelt upon the value to the medical man of a thorough grounding in the natural sciences, especially biology, zoology, and botany By this means a knowledge of the life habits of disease-conveying insects could be obtained and thus the most potent weapon in protection and defense be afforded. He showed how the possession of such knowledge was the means of great economic advantage, as well as in the direct saving of life, in connection with the settlement and development of new countries, and of the practical service rendered in an experience in West Africa. He pointed out the relative tolerance or immunity of the black to certain infectious diseases as compared to the white people, the former being the resistant hosts of a number of parasites and the latter acting as susceptible subjects.

At a stated meeting held January 14, Dr. Sidney J. Repplier exhibited a specimen showing "The Simultaneous Occurrence of Carcinoma and Sarcoma of the Breast." Dr. Wm. T. Cummins exhibited a specimen of "Colloid Carcinoma from a Boy Fourteen Years of Age." During life a tumor was discovered in the suprapubic region, and this on operation was found to originate from the peritoneum. The case terminated fatally, but an autopsy could not be secured, and the site of the primary growth could not be determined. Dr. Wm. Pepper exhibited "Microscopical Specimens Showing Phagocytosis in Malaria." Dr. Jay F. Schamberg exhibited "Microscopical Specimens of the Skin and Spleen from a Case of Indigenous Leprosy." Drs. A. J. Smith and H. T. Karsner exhibited "Microscopical Specimens of the Cutaneous Nodules from a Case of Leprosy." Dr. T. J. Gilchrist, professor of dermatology in the Johns Hopkins University, presented by invitation a communication entitled the "Histopathology of Experimental Urticaria Factitia," illustrated by lantern projection pictures. He showed how in from five to fifteen minutes after suitable mechanical irritation of the skin there occurred beneath the epidermis of the resulting wheal an escape especially of polynuclear and also of mononuclear leucocytes from the blood-vessels, with fragmentation and fibrin formation, and the presence of mast-cells and occlusion of the lumen of the sweat-ducts. These manifestations of the inflammatory process persist for about an hour, and then disappear. They are supposed to be due to the action of a toxic irritant set free in some as yet unrecognized manner. Dr. Harlan Shoemaker read a paper entitled "Observations on Prophylactic Inoculations Against Typhoid Fever."

Nutmeg Poisoning.—Cushing notes that cases of nutmeg poisoning in America, as reported by Wallace, occurred exclusively from the use of the crude nutmeg or mace; in many instances it had been used as an abortifacient, although it does not appear to have this action. As far back as 1576, Lobelius relates a case in which a woman was rendered delirious by nutmeg. The symptoms were drowsiness, stupor, diplopia; delirium frequently was present, and sometimes the first symptom was burning pain in the stomach, precordial anxiety, or giddiness. One case of death in a boy occurred after eating two nutmegs. The symptoms resembled those caused by cannabis indica. Professor Cushny showed how the powerful poison was contained in the oil of nutmeg, and it was the fraction which came over at 150° C., 14 mm. Hg; from this several bodies had been isolated—for example, myristicin. From experimental work, he came to the conclusion that the symptoms were to be attributed to action on the central nervous system, which was depressed, but exhibited some indications of stimulation in the form of restlessness, slight convulsive movements, and tremor. The oil also had a marked local irritant action, whether given by the mouth or hypodermically. The stomach wall was found red and injected; the urine often contained albumin.—*British Medical Journal.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 30, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	462	173
Diphtheria	369	43
Measles	505	18
Scarlet Fever	360	26
Smallpox	—	—
Varicella	234	—
Typhoid Fever	32	7
Whooping Cough	68	5
Cerebrospinal Meningitis	5	4
Malarial Fever	—	—
Totals	2035	276

New Elements in the Study of Cardiac Function in the Puerperal State.—C. Merletti made careful examination of the condition of the heart and blood pressure in women in the pregnant and puerperal state to determine whether there was any real ground for a belief that there was a change in the organic or functional heart condition due to pregnancy. He concludes that there is shown by cardiography, sphygmomanometry and sphygmography to be no organic change in the line of hypertrophy as has been supposed. There is some irregularity of the heart action which is due to reflex action on the cardiac mechanism. There is not any general rise in blood pressure. The functional power is normal, but immediately after labor there is some weakness of heart action which may cause thrombosis or asystole.—*Annali di Ostetricia e Gynecologia.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, for the weeks ending January 22 and 29, 1909:

		CASES.	DEATHS.
SMALLPOX—UNITED STATES.			
California, Los Angeles	Dec. 26–Jan. 2	2	.
San Francisco	Dec. 26–Jan. 2	3	.
Illinois, La Fayette	Jan. 4–11	7	.
Kansa, Topeka	Dec. 26–Jan. 2	5	.
Kentucky, Covington	Jan. 2–9	1	.
Maine, Van Buren	Jan. 2–9	4	.
Massachusetts, Taunton	Jan. 2–9	1	.
Minnesota, St. Paul	Nov. 1–30	38	.
Missouri, St. Joseph	Dec. 12–19	1	.
St. Louis	Jan. 2–9	1	.
Springfield	Dec. 1–31	1	.
North Carolina, in five counties	Nov. 1–30	23	.
Ohio, Cincinnati	Jan. 1–8	13	.
Tiffin	Jan. 2–9	1	.
Tennessee, Knoxville	Jan. 2–9	2	.
Texas, San Augustine County	Jan. 9	.	Present
Washington, Spokane	Dec. 26–Jan. 2	1	1
Wisconsin, La Crosse	Jan. 2–9	6	.
Milwaukee	Dec. 26–Jan. 9	15	.
SMALLPOX—FOREIGN.			
Arabia, Aden	Dec. 7–21	.	17

DIET AS A MEANS OF INCREASING VITAL RESISTANCE IN TUBERCULOSIS, WITH SPECIAL REFERENCE TO THE PROTEIN RATION.*

BY J. H. KELLOGG, M.D.,

BATTLE CREEK, MICH.

SUPERINTENDENT OF THE BATTLE CREEK SANITARIUM.

CHRONIC tuberculous infection is no longer regarded as a local disorder. Its presence is a certain indication of a weakening of the bodily defenses, a lowering of vital resistance, and a deterioration of the tissues which has rendered possible the growth and dissemination in the body of a parasitic organism which the healthy human body is perfectly able to arrest and to destroy.

It is evident, then, that of the several questions concerned in the battle against this greatest of all the foes of human life, the question paramount to all others is, How may bodily resistance be increased to that point which shall enable the tissues to defend themselves successfully against all comers in the shape of tubercle bacilli, whether bovine or human, or modifications of one or the other? The question of questions, in other words, is how to establish immunity and how to do this not only for a single individual, but for the community as a whole.

It is important to note just here that there are two kinds of immunity, the artificial immunity which is established by introducing into the body gradually increasing doses of the tubercle bacillus, or of the poisons produced by it, and the natural immunity which is the result of healthy blood, resistant tissues, a general state of organic vigor. The artificial immunity against tuberculosis has proved unsuccessful because of its short duration. Its employment is necessarily accompanied by considerable risk, so that it seems hopeless to look in this direction for a remedy for a race disease.

Trudeau's classic experiment points us in the right direction. After inoculating a number of rabbits with tuberculosis, he confined a number of them indoors and turned the others outdoors. The latter all recovered, while the former all died. This experiment shows that a rabbit living upon its natural food and under a natural environment is proof against tuberculosis. There is abundant reason to believe that this is equally true of man. In other words, tuberculosis is not one of the necessary evils of human life, but is a natural consequence of erroneous habits and departure from natural conditions. The marvelous success of the outdoor life in restoring to health thousands of tuberculous individuals demonstrates clearly how much may be accomplished by a return to natural conditions in one particular. Man is naturally an outdoor animal. A mole lives a healthy life in a burrow. A man must live in the fresh air and the sunshine.

But the purpose of this paper is to call attention to another primary condition of healthful life—proper and natural alimentation. Our bodies are made of what we eat. To be thoroughly healthy, possessing high resistance and natural immunity, the body must be supplied with proper material, with foods naturally adapted to the body needs. Upon the question of diet there is still very great diversity of opinion among those persons who specialize in the treatment of tuberculous affections. There is, indeed, such a wide diversity in the dietetic management of this class of cases by different physicians and in different institutions, as has been pointed out in the able and timely paper of Professor Irving Fisher, that it seems evident that some of the more important of these unsettled questions should receive early consideration, especially as the problem of nutrition is admittedly a fundamental one, and a factor which exercises a controlling influence in the battle of the tuberculous patient against his malady.

Twenty years ago it was impossible to compile data bearing on this question having sufficient scientific value to command consideration; but the more exact studies of nutrition which have been conducted in recent years have developed a great number of important and cogent facts which, when brought together, seem to justify important and clearly defined conclusions.

Prof. Fisher's tables show so great a divergence in the ration employed by different authorities that it cannot be a matter of indifference to the patient which ration is selected for him. For example, between the ration employed by Werner at the Roten-Kreuz Sanatorium (5,500 calories), and that of the Brompton Hospital, East Kensington, London (2,400 calories), there is a difference of 3,100 calories. Thus a patient on the Werner ration would be required to eat more than double the food consumed by a patient on the Brompton ration. It cannot be that both these patients have an equally good chance for recovery. Either one is half starved, or the other is enormously overfed. The difference in the protein ration is still greater than that of the total ration, being 410 calories at Brompton, and 1,200, or practically three times as much, at the Roten-Kreuz Sanatorium. If the Brompton patient receives as much protein as he is able to appropriate, certainly Werner's patients must be compelled to do an enormous amount of unnecessary renal work in the elimination of surplus nitrogenous wastes, to say nothing of other unnecessary burdens borne by vital organs whose perfect functioning is essential to vigorous life and high resistance.

*Presented before Section V of the International Congress on Tuberculosis, Washington, D. C., October 2, 1908.

Without professing to have wholly solved the problems under consideration, my purpose in this paper is to bring together a few facts which must have a direct bearing on the subject. The time allotted me will not permit of a complete survey of the question of diet in tuberculosis, hence I shall restrict myself to facts and considerations relating especially to the protein ration in this disease.

In the study of diet with reference to the dietetic management of pulmonary tuberculosis, or in relation to any equally grave disease, consideration must be given, first, to the effects of the particular diet suggested upon general nutrition, and, second, to any special relation which may exist between the diet suggested and the characteristic pathological conditions or tendencies of the disease.

RELATION OF THE PROTEIN RATION TO GENERAL NUTRITION AND VITAL RESISTANCE.

Within the last ten years there has been a manifest trend of opinion among physiologists toward the recognition of a lower standard for the protein ration in ordinary conditions of health. The observations of Chittenden, Mendel, Folin, Gautier, Hirschfeld, Klemperer, Bourdet, Lapicque, and numerous others have shown conclusively that the nitrogen balance may be maintained under ordinary conditions of life, and even that an actual gain in strength and physical vigor may take place, under a ration furnishing not more than one-half or even one-third of the amount of protein required by the older standards. For example, Chittenden, in an experiment upon twenty-six men—sixteen soldiers, six athletes, and four college professors—extending over a period of nine months, was able to show a distinct gain in health, strength, and general vigor on a dietary which furnished .625 grams, or 2.56 calories of protein, per kilogram of body weight. In this experiment he was himself one of the subjects, and reduced his protein to about 31 grams, and has since continued the same ration for several years, with evident advantage.

Hirschfeld, who weighed 73 kilograms, 16 kilograms more than Chittenden, maintained himself in nitrogenous equilibrium with 43.3 grams of albumin per diem, .60 grams, or 2.46 calories per kilogram of body weight—even less than the Chittenden standard. Klemperer reduced the nitrogen intake to .47 grams of albumin (1.90 calories) per kilogram of body weight. Bourdet maintained that .75 grams of albumin (3.07 calories) per kilogram of body weight is quite sufficient. Folin maintained body weight and muscular strength for ten days on a diet in which the nitrogen was reduced to one gram per diem.

The writer is able to add from his own observations and experience a number of facts which he has thought it worth while to place on record. Early in life, circumstances led me to adopt a low protein dietary which has now been followed for more than forty-two years. During this period flesh meats have been excluded from my dietary, and for about half of the time eggs and milk have also been excluded almost entirely, so that my dietary has practically consisted of such quantities of protein as are naturally found in bread, fruits, potatoes and other vegetables, with the occasional use of nuts.

I have enjoyed some special advantages for the study of dietetics through the fact that for thirty-two years I have had charge of a medical institution in which a low-protein dietary is made an essential part of the régime for both patients and employees. In this institution there are employed 30 physicians, over 250 nurses and medical students, and between 500 and 600 other persons. During the 32 years the number of different persons employed has been between 10,000 and 12,000.

Some ten years ago (1898) a dietary study was made for the purpose of determining the proportions of protein, fats, and carbohydrates, consumed daily by our workers. The experiment included some 265 persons, 125 men and 140 women.

The figures obtained for protein were considerably below many of the old standards, though above the standard recently established by Chittenden and others. More recently the amount of protein consumed has been considerably reduced. This has been the result of the study of Chittenden's work and the introduction of a larger amount of fat into the dietary, which was evidently needed.

TABLE I

SHOWING THE RESULTS OF A DIETARY STUDY OF 125 MEN AND 140 WOMEN DURING 14 DAYS

	Men (Average)		Women (Average)	
	Grams	Calories	Grams	Calories
Protein	84.82	348	76.54	314
Fats	36.78	360	30.05	279
Carbohydrates	453.49	1,859	447.44	1,834
Total	577.09	2,567	554.03	2,427
	Kilos		*Kilos*	
Average weight at beginning	61.2		54.1	
Average weight at end	61.5		54.1	
Average gain	0.3		0.0	
Average gain in strength of ten selected persons	225		68.6	

The work required of physicians and nurses in the institution is very exacting. The hours are long and the work itself is hard, especially during the summer months. Notwithstanding, it is very exceptional that physicians and nurses do not improve in health after becoming connected with the institution, and there is a noticeable exemption from such common maladies as appendicitis and other intestinal disorders, skin diseases, pneumonia, and infectious maladies. Twenty years ago cases of tuberculosis occasionally developed among the employees, but since the introduction of a larger proportion of fat into the dietery this tendency has disappeared. There is generally a noticeable improvement in the appearance of persons who make a change to a low protein dietary on becoming connected with the institution. The skin becomes clearer; acne, when present, disappears, and there is usually a gain in flesh and in endurance.

A low protein diet does not deteriorate the blood.—A study of the blood and blood pressure in 100 of our nurses and assistants, made at my request by Dr. J. T. Case, gave the following average results:

TABLE II

	40 Men	60 Women
Hemoglobin (dare)	97.0%	96.3%
Red Corpuscles, per c.mm.	4,790,000	4,290,000
White corpuscles, per c.mm.	7,353	7,023
Color index	101	102
Blood-pressure (Stanton instrument; narrow armlet)	132.5 mm.	119.8 mm.
Pulse (standing)	76	76

The above figures certainly show no tendency of a low protein ration to deteriorate the blood, and entirely agree with the observations on endurance made by Prof. Irving Fisher, of Yale University,

the results of which will be given later in this paper.

The Urine in Low Protein Subjects.—Within a year a careful study has been made of the urine in 46 subjects, 24 men and 22 women, for the purpose of determining normal standards of persons living upon a low-protein ration. The subjects employed in this study were placed upon a ration which furnished .80 grams of protein, 1.10 grams of fat, and 4.80 grams of carbohydrates for each kilogram of body weight. Flesh foods of all sorts were excluded. The quantities obtained by Folin with an ordinary mixed or high-protein diet are given in the table for the purpose of comparison. It should be stated that both the men and the women were healthy persons between the ages of 20 and 30 years, all engaged in active duties as nurses and office or laboratory assistants. The table gives the average of all the subjects.

TABLE III*

		Ordinary or High Protein Diet (Folin)	Low Protein Diet Without Meat
Quantity	c.c.	1,430	1,000
Specific gravity		1.015	1.018
Freezing point		—	4.287
Urinary depuration			
Acidity in terms of H_3PO_4	gms.	2.01	.940
Total nitrogen	"	16.140	6.440
Urea	"	29.80	11.650
Uric acid	"	0.370	0.323
Ammonia, in terms of NH_3	"	.850	.247
Creatinin	"	1.550	.815
Chloride	"	10.050	5.455
Phosphates, terms of P_2O_5	"	3.870	1.455
Total sulphates, terms of SO_3	"	3.110	1.071
Ethereal sulphates, in terms of SO_3	"	.220	.116
Total sulphur, in terms of SO_3	"	3.310	1.399
Neutral sulphur, in terms of SO_3	"	.170	.192
Indican (Fehling's solution = 100)		77.00	5.60

*The technical chemical and other detail work involved in the preparation of this table, was chiefly done at the author's request and under his supervision, by Drs. E. H. Risley, Paul Roth, and Jean W. Morse. The author also takes pleasure in acknowledging his indebtedness for various courtesies extended by Professors L. B. Mendel, R. H. Chittenden, Otto Folin, and C. A. Herter, in admitting his assistants to their laboratories for special instruction and the verification of technical methods; and to Professors Francis G. Benedict, N. Zuntz, and Irving Fisher for valuable suggestions and information.

These facts afford the most indubitable evidence of the diminished work required of the liver and kidneys in dealing with waste and toxic products under a low-protein dietary. Such an advantage ought to become apparent, especially in tests of endurance. Prof. Irving Fisher, of Yale, was quick to recognize this fact when he first visited Battle Creek about four years ago, and he some time later devised and applied a series of tests for the purpose of determining the effect of high and low-protein dietaries upon muscular endurance. In this experiment a number of our young men who had been for months or years accustomed to a low-protein dietary were submitted to a series of severe tests, which were afterward applied to a considerable number of Yale University athletes who were accustomed to the ordinary high-protein dietary. The results of this endurance test were published by Prof. Fisher in the *Yale Medical Journal* of March, 1907, from which I make the following brief extracts summing up the results:

"In the absence of any exact mechanical method of measuring endurance, three simple endurance tests were employed—first, holding the arms horizontally as long as possible; second, deep knee bending; third, leg raising with the subject lying on the back. All of these tests were made before witnesses. . . . The first comparison (for arm holding) shows a great superiority on the side of the flesh-abstainers. Even the maximum record of the flesh-eaters was barely more than half the average of the flesh-abstainers. Only 2 of the 15 flesh-eaters succeeded in holding their arms out over a quarter of an hour; whereas 22 of the 32 abstainers surpassed that limit. None of the flesh-eaters reached half an hour, but 15 of the 32 abstainers exceeded that limit. Of these, 9 exceeded two hours, and 1 exceeded three hours. . . . In respect to deep knee bending, if we take the number 325 for reference, we find that, of the 9 flesh-eaters only 3 surpassed this figure, while of the 21 abstainers, 17 surpassed it. Only 1 of the 9 flesh-eaters reached 1,000, as against 6 of the 21 abstainers. None of the former surpassed 2,000, as against 2 of the latter. . . . In respect to leg-raising, the records show little difference. . . . The results indicate that the users of low-protein and the non-flesh dietaries have far greater endurance than those who are accustomed to the ordinary American diet."

TABLE IV.

SHOWING RESULTS OF TESTS CONDUCTED BY PROF. IRVING FISHER TO DETERMINE THE INFLUENCE OF HIGH-PROTEIN AND LOW PROTEIN DIETARIES UPON ENDURANCE.

Arm-Holding Test

Low-Protein Subjects, 32; High-Protein Subjects, 15

		Per Cent
Low-protein subjects, average minutes	49	
High-protein " " "	10	20
Low-protein " maximum "	200	
High-protein " " "	22	11
No. of low-protein subjects who exceeded 15 minutes	22	69
" " high-protein " " " 15 "	2	13
" " low-protein " " " 30 "	15	47
" " high-protein " " " 30 "	0	0
" " low-protein " " " 60 "	9	28
" " " " " 180 "	1	
Total minutes' work done by 15 low-protein subjects	1,336	
" " " " 15 high-protein athletes	150	11.2

Deep Knee-Bending Test

Low-Protein Subjects, 21; High-Protein Subjects, 9

		Per Cent.
Low-protein subjects, average number times	833	
High-protein " " "	383	46
Low-protein " who surpassed 325	17	81
High-protein " " " 325	3	33.3
Low-protein " " reached 1,000	6	28.6
High-protein " " " 1,000	1	11
Low-protein " " " 2,000	2	9.5
High-protein " " " 2,000	0	0
Low-protein best subjects (9) number times	12,335	
High-protein athletes (9) number times	3,447	28

The figures given in the tabulated results of Prof. Fisher's tests (Table IV.) and the analysis of the results by Prof. Fisher, above quoted, demonstrate that persons subsisting upon a low-protein dietary are in no degree inferior in endurance to those subsisting upon a mixed or high-protein dietary, but are on the contrary much superior.

Fifteen of the low-protein subjects did nine times as many minutes in the arm-holding test as did an equal number of the high-protein athletes, although only three or four of their number had had any athletic training, the other subjects being men of sedentary habits, while the high-protein men were all experienced athletes in training for athletic contests. In other words, the untrained meat abstainers showed nine times as much endurance as the trained flesh-eating athletes.

In the deep-knee-bending test the untrained flesh-abstainers showed nearly four times as much endurance as the trained flesh-eaters or high-protein subjects.

This fact was made still clearer by the performance at a later period of one of our nurses, who made the deep-knee bend 5,002 times, or 3,773 times more than the best performance of the high-protein athletes and 1,555 (nearly fifty per cent.) more than the entire nine flesh-eating athletes, or thirteen times as many as the average of the high-protein athletes. This subject was a young man of twenty-two years who had lived upon a low-protein and fleshless dietary for about two years.

Experiments in the French army clearly demonstrate, according to Major P. Joly, that the reduction of the protein ration to the extent of 120 grams, substituting therefor 120 grams of carbohydrates (cane sugar), resulted in a marked improvement in the health of the men who were subjected to severe muscular exertion. The effect of this lowering of the protein ration was a decrease in the number of heartbeats and respiratory movements, a marked increase in endurance, and a decrease of the sick rate. Men were found to be able to endure the heat and fatigue of marching and maneuvers much better on the low-protein ration than on the higher ration.

The average number of guests at the Sanitarium during the last thirty-two years has been between 3,000 and 4,000 yearly, making about 100,000 persons in all who have been subjected to a low-protein dietary. The present number is about 7,000 annually. For the last three years the Chittenden standard of .80 grams of protein per kilogram of body weight has been followed. No injurious results have been observed, but instead a very decided improvement in the proportion of recoveries and in the rate of improvement.

The cooking and serving of foods and the bills of fare are so arranged that the number of calories of protein, fats, and carbohydrates taken at each meal and for the day may be easily determined, and the advantages of a low-protein dietary are so manifest that both physicians and patients readily adopt and adhere to the new standard. The following results have been particularly noticeable:

1. Clearing of the skin; the disappearance of skin eruptions, sallowness, etc., and rapid improvement in color and texture of the skin.

2. Improvement in the blood count and in hemoglobin, as shown in Table V.

TABLE V.

SHOWING THE EFFECTS OF A LOW-PROTEIN DIETARY UPON THE BLOOD IN CHRONIC INVALIDS.

	Before Treatment	After Treatment	Gain, Per Cent.
Average blood count in 1,000 consecutive cases.	3,885,200	4,359,340	12.2
Hemoglobin.	73 3%	88 4%	15.1
Blood count in 30 cases of anemia	1,989,600	3,140,000	58.2
Hemoglobin in 30 cases of anemia	47%	67%	20.0

The numerous observations made in the last twenty years have shown the correctness of the practice recently inaugurated by Prof. Krauss, of Berlin, who recommends a low-protein dietary in pernicious anemia, suppressing entirely the use of flesh meats in such cases.

3. Another important effect observed has been a noticeable fall in blood pressure in cases in which it was, on arrival, much above normal. This has been noted particularly in the first two or three weeks after arrival. While a low-protein ration has been found quite sufficient to maintain the blood pressure at the normal standard, it has shown itself to be a most efficient agent in lowering the blood pressure when abnormally high. In over 33,000 blood pressure determinations carefully made, it has been almost uniformly observed that a decided fall in blood pressure occurs within a few weeks after the adoption of the low-protein dietary in cases in which the blood pressure is at the beginning abnormally high. The instrument used in taking the blood pressure is the Stanton modification of the Riva-Rocci apparatus. The observations were all made between 12 M. and 1 P. M. The average pressure in 138 cases in which the blood pressure was above normal was 181; later, or at the time of discharge, the average pressure was 158, a fall of 23 millimeters of mercury, which I believe may be justly attributed, in chief part, at least, to the low-protein dietary, through suppression of pressure-raising toxins produced in the alimentary canal, and the better elimination of tissue wastes. No pressure-lowering drugs were administered.

The facts above stated would certainly seem to indicate that a low-protein dietary exercises a decided influence in improving general bodily conditions. The improvement in the conditions of the blood and the blood-vessels, in the appearance of the skin, in muscular and nervous endurance, in greatly lessened development of toxins in the body, as shown by the urine, are facts which all point toward a decided improvement in vital resistance.

Numerous other facts well known to physiologists show the advantage of a low-protein dietary as regards endurance and vital resistance. For example, East India surgeons have frequently remarked the extraordinary ability of the rice-eating natives of India to undergo very severe surgical procedures, recovering under conditions which would almost certainly prove fatal to a European accustomed to a high-protein dietary. Captain Sanderson, the famous elephant hunter of India, in his charming volume, "Fourteen Years in the Jungle," makes the observation that antelope were often encountered carrying about great festering sores, the results of terrible wounds inflicted by lions and tigers, yet apparently in excellent condition; while a small bullet wound in a leg was almost certain, sooner or later, to prove fatal to a tiger or lion through blood-poisoning.

The hunters of the Rocky Mountains and of the Scottish Highlands feed their dogs upon a very low-protein, non-flesh diet. When asked by the writer what he gave his dogs to eat, a Scotch hunter remarked, "The same as I eat myself, sir—brose, bannocks, and potatoes."

Paget believed that the higher death rate from surgical operations in cities, as compared with rural districts, was due to the high-protein dietary of the urban population. Lauder Brunton attributed the greater frequency of death from chloroform anesthesia in England, as compared with India, to the high-protein dietary of the English people. The runners of East India, the miners of Mexico, the swift-footed Tarahumaris of the Sierra Madre Mountains, who sometimes run 175 miles in 24 hours over steep mountain paths, also subsist upon a very low-protein diet, and accomplish feats of endurance which have never been equaled by persons subsisting on a high-protein dietary.

Modern researches confirm the conception of Liebig that protein is essentially a tissue-building substance, and not primarily intended for body fuel. A dog fed upon lean meat free from fat requires a ration having a much higher caloric value than when fed upon a diet consisting largely of fats and carbohydrates, thus showing that as a source of energy protein is much inferior to fats and carbohydrates. The relation of the two classes of food principles appears to be essentially the same as that of metal repairs and coal to the locomotive. The value of protein other than as a source of material for the repair of living tissue seems to be rather incidental and greatly inferior to that of carbohydrates and fat.

Professor N. Zuntz, of Berlin, recently informed the writer that experiments made by himself and his associates have shown that protein requires a much greater expenditure of energy in its digestion and utilization than does any other food principle. For example, the energy required for the digestion of fats is only 2½ per cent. of the total energy represented. In the case of starch the energy expended in digestion is 10 per cent. of the total; while protein requires an expenditure of 16 per cent. of the energy represented. That is, protein requires an expenditure of 1.6 times as much energy in its utilization as does starch, and 6.4 times as much as does fat in proportion to the amount of energy supplied.

It cannot be doubted, of course, that reduction of the protein below the actual needs of the body causes a depreciation of vital resistance, through disturbance of the nutritive balance. The same is true with reference to any other food principle; but the question under discussion is not the effect of an actual deficiency of protein, but the effect of an excess.

There are still other facts bearing upon the question which the writer believes to be even of greater importance. Vital resistance depends more directly upon the blood than upon any other factor concerned in the body defense. That wisest of law givers and most sagacious of sanitarians, Moses, declared, "The life is in the blood," and John Hunter's experiments showed the scientific accuracy of the ancient Hebrew's dictum.

Roger, Charrin, Bouchard, Schiff, Cohnheim, Minkowski, Roux, Nocard, Fraenkel, Helmann, and others have shown us how immediately and positively vital resistance fluctuates with changing conditions of the vital fluid. Says Charrin "The alkalinity of the body fluids is synonymous with organic protection." The blood of an animal subjected to a high protein dietary is overcharged with protein wastes because of the excess of protein ingested. The result is deficient oxidation of protein wastes, and a marked diminution in the alkalinity of the blood. With this diminished alkalinity is associated, as a necessary consequence, diminished vital resistance. This condition of the blood is indicated by an excessive quantity of urea and uric acid and a high degree of acidity of the urine. In a healthy man upon whom I experimented some years ago the urea and uric acid were quadrupled within a week on a heavy meat diet. The burden thrown upon the liver and kidneys by this excess of protein must have been increased in the same proportion.

The difference in the character of the products of protein metabolism and those of the metabolism of fats and carbohydrates is a matter that seems worthy of consideration. The CO_2 resulting from the combustion of fats and carbohydrates is quickly eliminated through the lungs. On the other hand, the products of protein metabolism, nitrogen compounds highly toxic in character, require for their elaboration and elimination a very considerable amount of work, in which not only the liver and kidneys are concerned, but the adrenals, thyroids, and various other organs.

The elimination of CO_2 through the lungs and skin apparently has no injurious effect upon these organs; whereas the circulation through the liver and kidneys of an excess of the poisons which find their natural exit through the urine, and which are prepared for elimination by the liver, unquestionably give rise to irritation which sooner or later results in grave disease.

A Low-Protein Dietary Does Not Lower the Tuberculo-Opsonic Index.—Sir Michael Foster's observation that the tuberculo-opsonic index was reduced under a very low-protein dietary proves nothing in favor of an excessively high-protein ration. At my request, our bacteriologist, Dr. A. W. Nelson, has determined the opsonic index in twenty-six of our nurses and others connected with the institution who have for some years (two years to forty-two years) lived upon a low-protein dietary, having eaten no flesh food during that time. The tuberculo-opsonic index was found to range from .87 to 1.95. Only three out of the twenty-six persons tested were found with an index below normal. These were .87, .92 and .98, respectively. The average was 1.26. In a case of phthisis pulmonalis now under observation, the opsonic index rose on a low-protein dietary (Chittenden standard) from .47 to 1.47 in four weeks. These figures certainly do not indicate any depreciation of resistance to tuberculous infection as the result of a low protein dietary.

Relation of Intestinal Autointoxication to Tuberculosis.—Another question which it seems pertinent to raise is whether too exclusive attention has not been given in the study of the protein ration to the question of tissue metabolism. The careful study of the bacterial flora of the intestine which has been made within recent years by Escherich, Tissier, Metchnikoff, Herter, Levin, Roger, Adami, Cohendy, Gilbert, Dominici, Strassberger, and others has shown the immense influence exerted upon the functions and tissues of the body by bacterial toxins formed within the alimentary canal. Absorbed into the portal blood these poisons are circulated through the liver, where they are in part oxidized and rendered innocuous, and find their way out through the lungs, skin, and especially the kidneys. These investigators and others have shown that there is a close relation between the protein ration and intestinal putrefactions.

Pasteur supposed that bacteria were a necessary aid to intestinal digestion and essential to both animal and plant life. His pupil, Roux, showed that beans may grow in a sterile soil. Nuttal and Thierfelder kept guinea-pigs alive in a sterile medium. Levin examined 480 animals at Spitzbergen,—bears, seals, reindeer, and other animals,—53 species, and established the fact that in the Arctic region the intestines of mammals are usually sterile.

It seems to be finally settled that bacteria are not necessary for the maintenance of animal life, and certainly that putrefactive bacteria are not only unnecessary, but harmful. Nevertheless, these bacteria are present in the intestine in enormous quantities. Gilbert calculates the number of bacteria daily discharged from the body at 12 trillions. Strassberger makes the number 120 trillions. Roger enumerates 240 species of bacteria which have been found in the human intestine. Many of these produce substances which are in the highest degree toxic. On a high-protein diet, the poison-forming bacteria rapidly increase, giving rise to intestinal autointoxication. German medical authorities have been rather slow to recognize this condition, but Senator, Backmann, Mester, Brieger, Hoppe-Seyler, Krauss, Ewald, Jaffé, Albu, Hirschler, Munch, Rovighi, Grawitz, and others have recognized the validity of the teaching of Bouchard, and have expressed views in harmony therewith.

The writer has for some years pursued studies in relation to this question, and recently by the aid of the improved methods of Herter, Folin, and other recent investigators, has made several observations which seem to have a practical bearing. Five healthy young men were fed upon various diets, as indicated in the tables presented herewith, and a careful study was made of the stools and the urine. In making these studies the stools were examined both chemically and bacteriologically. By plate cultures and Gram staining, the number of aërobes and anaërobes per gram of dried feces was determined, and by means of the useful method of L. Rettger, the same determination was made respecting the number of putrefactive organisms. By distillation of a portion of the feces and testing by Herter's method, the amount of indol produced was determined in each specimen. This determination was made quantitatively by means of a calorimetric scale carefully worked out by my colleague, Dr. Risley. The urine was examined, and a careful determination of the amount of indican present was made by Folin's method.

The amount of the daily ration was from 1,800 to 2,400 calories. The principal carbohydrates were bread and potatoes. Fat in proportion of about 30 per cent. of the total ration was taken in the form of butter. The protein ration was varied from 125 to 450 calories. The amount of protein per kilogram of body weight was varied from .50 grams to 1.80 grams. The lower quantity was in connection with a fruit and cereal diet. Each special dietary was closely followed for five to eight days, and was employed with two or more persons, and in several instances repeated a number of times. The figures given in the accompanying table are the averages obtained from all the observations made, the number of which is indicated in each case.

TABLE VI.

Showing the Amount of Intestinal Putrefaction as Indicated by the Amount of Indol Found in the Feces and of Indican in the Urine with the Several Diets Indicated.

	Daily Rat'n in Calories	Gms. of Protein per Kilo of Body Weight	No. of Observations	Avg. Amt Indol in Feces, No. Mgms.	Avg. Indican in Urine (Folin Scale)
Group I—Moderately high protein diet, 1.00 grams or more per kilo. of body weight	2,187	1.00–1.80	39	1.2270	6.00
Group II—Low-protein diet (vegetable)	2,064	.49–0.90	74	.3611	0.00
Group III—Low-protein diet below Chittenden standard (vegetable)	2,040	.49–0.80	51	.1227	0.00
Group IV—Fruit and cereal diet	2,075	.49–0.70	38	.0567	0.00
Group V—High-protein diet —meat and vegetables	2,200	1.57 1.80	10	1.3508	9.5

It is most clearly shown by the above tables, giving the results of 212 observations, that the amount of intestinal putrefaction is directly proportional to the amount of protein in the dietary. With a moderately high protein ration of 1.06 to 1.80 grams per kilo of body weight, the indol of the feces was ten times as much as on a low-protein diet (Chittenden standard). On a meat and vegetable diet, affording 1.57 to 1.80 grams of protein per kilo of body weight, the indol was increased eleven fold. The amount of indican found in the urine with the high-protein dietaries bears further witness to the increase in putrefaction with increase of protein in the food. With a fruit and cereal diet the indol was reduced to less than one twenty-fifth of the amount found with a mixed high-protein diet.

The results expressed in the table are much more strongly shown in the protocols. For example, while taking a high-protein meat ration, the subjects of experiment not only showed an increase of indol to ten or even twenty times the amount previously present when on a low-protein diet, and a corresponding quantity of indican in the urine; but they experienced very decided discomforts and inconveniences arising from the increased toxicity of the intestinal contents. The usual symptoms were headache, drowsiness, loss of appetite, loss of energy, and general malaise. In every case the subjects of these experiments were very glad to return to their accustomed low-protein dietary.

Results identical with the above have been obtained by others who have studied this question, among whom should be especially mentioned Combe, Mester, Backmann, Salkowski, and Jaffé. The two latter have shown that the intestinal putrefactions increase in proportion to the amount of albumin ingested. Müller and Ortweiller showed that on a meat diet products of bacterial putrefaction in the intestine increase and that aromatic substances, especially indol and phenol, appear in considerable quantities in the urine.

Backmann showed the same to be true of white of eggs, but much less so than with meat, as indicated by the following table:

	Conjugate Sulphates
1 Ordinary diet	0.167 grams
2 " " plus 200 grams of eggs	0.184 "
3 " " " 120 " " meat	0.234 "

Mester compared fresh meats and "prime" meat with the following result:

	Conjugate Sulphates
1 Ordinary food	0.058 "
2 " diet plus meat	0.113 "
3 " " prime meat	0.328 "
4 " " " meat in advanced decay (high)	0.694 "

A second series of observations was carried on collaterally with the above. To various mixtures of foods of equal weight (25 grams) was added a definite quantity (10 grams) of feces which had been previously examined for indol and bacteria. The whole was then placed in an incubator at body temperature for three days. The quantity of indol produced was determined by distillation and testing by Herter's method.

TABLE VII.

Showing the Amount of Indol Produced in Equal Quantities of Various Foodstuffs (25 Grams) Mixed with 10 Grams of Human Feces and Incubated for Three Days.

Meats	Indol, Mgms.	Milk Products	Indol, Mgms.
Dried beef	2.71	Unboiled milk	.620
Smoked herring	4.30	Boiled milk	.520
Dried codfish	4.90	Yogurt cheese	.126
Salmon	5.91	Cheese	2.910
Sardines	7.35	Average	1.045
Beef (fresh)	12.42		
Pork (fresh)	13.72	*Vegetable Foods*	
Mutton (lean)	17.02	Cereals (average of 20)	.055
Average	8.54	Raw vegetables	.147
		Cooked vegetables	.078
		Cooked fruits	.222
		Bananas	.404
		Average	.181

The table shows that the vegetable foods on an average produced only about two per cent. as much indol as the average produced by flesh foods, while the best vegetable foods, the cereals, produced only .3 per cent. as much indol as the most toxic flesh food, mutton. Milk products, including ordinary cheese—a very questionable food—produced 12 per cent. as much indol as average meats, but omitting ordinary cheese produced only seven per cent. as much, while yogurt cheese, made with

the *Bacillus bulgaricus*, made least indol of any substance examined.

These results are entirely in harmony with the results obtained in the feeding experiments, and taken with them show very clearly that foodstuffs which undergo putrefaction outside the body when brought in contact with colon bacteria produce when ingested a very marked increase of the intestinal putrefactions.

The above facts seem to furnish abundant reason for holding that a high-protein diet tends very decidedly to weaken general vital resistance through the enormous extra burdens which it imposes upon the liver and other poison-destroying glands, and upon the kidneys, the most important of poison-excreting glands. May we not, then, justly raise the question whether in the high-protein feeding of patients suffering from pulmonary tuberculosis, considerable risk may not be run of doing the patient harm by lessening his ability to resist the further encroachments of his malady or to repair the damages already done?

SPECIAL PATHOLOGICAL CONDITIONS PRESENT IN PHTHISIS PULMONALIS WHICH CONTRAINDICATE A HIGH-PROTEIN DIETARY.

The marked tendency of the tuberculous patient to loss of flesh and to the development of anemia has naturally directed special attention to the importance of encouraging the fat-building and blood-making processes of the body. But there are other indications which are equally deserving of attention and which should be permitted to influence the dietetic management of these cases. The materials ingested must be metabolized and eliminated as well as digested and absorbed. Incidentally, while undergoing digestion, they may also undergo fermentations and putrefactions which may so change their nature as to render them not only useless as nutrients, but toxic and in the highest degree damaging. Hence the welfare of the liver and other toxin-destroying glands and of the kidneys, poison-eliminating glands, must be considered as well as the need of the organism for an increase of adipose tissue. A simple increase in the thickness of the panniculus adiposus cannot be of any very great advantage to a man whose body has been invaded by a vast army of tubercle bacilli. Before the infection took place there had been a depreciation in vital resistance, a deterioration of tissue and function which made the invasion possible and with each advance of the disease, this weakening of the ability of the organism to battle against its foes is lessened. Recovery can be secured only by improving the integrity of tissue and function to such a degree that the ability of the organism to combat its assailants will be raised higher than before the invasion occurred.

The average subject of tuberculous infection presents a number of special pathological conditions which must be considered in preparing a therapeutic regimen. Among these may be especially enumerated the following:

1. *Diminished "alkalinity" of the blood* (Lawrason Brown).—This signifies diminished vital resistance, diminished efficiency of the blood as a germicide, diminished power to develop immunity, diminished power to repair damaged tissues, diminished power to oxidize wastes. Anything which tends still further to diminish the alkalinity of the blood must be to that degree a hindrance, rather than a help, in the battle of the organism against the tubercle bacillus. One of the notable and constant effects of a high-protein dietary is to diminish the alkalinity of the blood.

2. *Diminished hepatic efficiency.*—In consumption the liver is nearly always seriously crippled. Ullom declares that passive congestion of the liver is found in nearly every case of pulmonary tuberculosis. This is the natural result of diminished respiratory activity, since the venous circulation of the liver is largely influenced by the movement of the chest in respiration. To the evidences of chronic passive congestion of the liver are added, according to Ullom, many other evidences of a lowered vital state in this organ, among which are amyloid and fatty degeneration, tuberculous infection, and fibrosis or cirrhosis. Ullom expresses the opinion that fibrosis of the liver is not due to the tubercle bacillus, but to "other etiological factors." Boix and others have shown what these factors may be. According to Boix the toxins formed as a result of putrefactive processes in the intestine are the chief cause of hepatic fibrosis. He was able to produce cirrhosis of the liver in rabbits by mixing with their food cultures of colon bacilli and also by feeding them extracts of feces.

That a high protein ration, that is, a dietary consisting largely of flesh foods, favors hepatic congestion, is a fact long known to physicians. A diet which encourages intestinal putrefaction and an abundant anaërobic flora in the intestine, must in the highest degree encourage hepatic congestion and various functional and organic changes in the liver, and thereby break down this important defensive barrier and prepare the way for its invasion by the tubercle bacilli. It need not, then, be a matter of surprise that Ullom found in thirty-seven autopsies in cases of pulmonary tuberculosis, a tuberculous condition of the liver in 81 per cent. of the cases. Fatty degeneration of the liver was found in 24 per cent. of the cases, and in only two cases (5.4 per cent.) was the liver found approximately normal; that is, the liver was found diseased in 94.6 per cent. of the cases. Arnold reported tuberculosis of the liver as an almost constant finding in pulmonary tuberculosis. Simmons reported tuberculosis of the liver in 78 per cent.

The passive congestion of the liver which naturally results from the overwork of the right heart and the diminished mobility of the chest, together with the special exposure of the liver to infection through the portal circulation and the extra work required of it in metabolizing the excessive nitrogenized waste which accompanies the febrile stage of pulmonary tuberculosis, certainly suggest the importance of guarding the integrity of this vitally important organ in every possible way, and contraindicate a high-protein dietary which imposes exaggerated and unnecessary hepatic work.

3. *Degeneration of the Thyroid Gland.*—Entirely in harmony with the consideration presented above is the interesting fact to which Roger, Garnier, De Quervain, Sarbuch, and others have recently called attention, viz., the occurrence of general sclerosis of the thyroid gland without tuberculous lesions of the gland itself in cases of tuberculosis affecting other parts of the body.

In a case of tuberculosis of the lungs reported by Carnot and Delion, death occurred from tetany, and post-mortem examination showed caseous degeneration of the parathyroids. This condition of the thyroid and parathyroid is attributed to "the effect of the action of the diffusible toxins produced

by the tubercle bacilli." It is well known that other toxins, especially those produced by putrefactive changes in the intestine, are capable of producing diseased conditions of the thyroid, the natural result of the overwork of the glands resulting from excessive saturation of the blood with these toxic substances.

The enormous burden added to the labor of the defensive organs of the body by a high-protein diet, and the great injury which must result when these organs are weakened, is illustrated by what happens when certain toxin-destroying glands are removed from the body or rendered functionally inactive. It is well known, for example, that the removal of the thyroid gland (Breisacher, 1890) of a dog is quickly followed by the death of the animal if it is fed upon a meat diet while life is prolonged indefinitely and the animal enjoys good health when fed upon a diet of bread and milk. When such a dog is fed upon meat which has been well boiled, it suffers less and lives much longer than when fed upon raw meat evidently because of the removal of poisonous meat extractives in the boiling. Blum holds that the function of the thyroid gland is to neutralize poisons derived from the putrefaction of albumin in the intestine. Kishi holds that the thyroid destroys a poisonous substance, a nucleoprotein which is formed in the intestine after the ingestion of meat.

These facts are alone sufficient to condemn a high protein flesh diet in a disease in which the thyroid gland is already overworked, and in which it is likely to be seriously crippled. Is it not possible, indeed, that the effect of such a diet in a case of pulmonary tuberculosis with degenerated thyroids may be almost as deadly as in dogs deprived of their thyroids?

In the ingenious Eck fistula experiment an anastomosis is made between the portal vein and the vena cava, a ligature being applied to the portal vein close to the liver, thus cutting out the liver from the portal circuit. A dog thus prepared and fed upon meat dies in three days; when fed upon a diet of bread and milk, the animal lives in excellent health for an indefinite length of time. The urotoxic coefficient of such a dog was found to be increased to nearly three times the normal after the tying of the portal vein, from which the conclusion may be drawn that with a high-protein meat diet the poison-destroying work of the liver and of the body is three times as great as on a low-protein or non-flesh dietary. (Urotoxic coefficient before ligature, .344; after ligature, .902—Pawlow.)

4. *Disease of the Adrenals.*—Authorities agree in regard to the great frequency with which the adrenals are involved in connection with tuberculous affections of the lungs. The relation of these glands to oxidation, to general vital resistance, and to the toxin-destroying functions of the body gives great significance to this fact. Behring showed that blood serum (sheep's) possessed sterilizing properties far superior to those even of the stronger solutions of carbolic acid and corrosive sublimate, which were formerly employed in surgical operations. This property of the blood being, very probably, largely due to the adrenals, as well as the ability of the blood and tissues to oxidize or destroy toxins, it needs no argument to indicate the importance of promoting intestinal asepsis in all possible ways in pulmonary tuberculosis, and especially by avoiding a dietary which must flood the blood and the tissues with toxic products to an extraordinary degree.

5. *Concurrent Disease of the Kidneys.*—Drs. Flick and Walsh state that "nephritis occurs very frequently in tuberculosis." Among the causes they mention the effects of "the toxin excreted through the kidneys from lesions elsewhere." Grancher and Martin produced nephritis in dogs by attempts to establish immunity with increasing doses of tubercle bacilli. "The longer the animal lived and the higher the resistance it attained, the greater were the chances of nephritis." Drs. Flick and Walsh regard nephritis as "one of the complications in tuberculosis most to be dreaded;" and especially "because it is a complication which comes through the very process which leads to recovery, namely, immunization." These eminent observers assert that "many patients with tuberculosis die by way of nephritis as the real cause of death" and indicate as the symptoms pointing toward nephritis, " a pasty skin, unusual fatigue upon slight exertion, shortness of breath, high specific gravity of urine, hyalin and granular casts, albumin, etc."

The Third Annual Report of the Phipps Institute, 1905, contains an exceedingly interesting report by Joseph Walsh of the autopsy findings, from which it appears that 84 per cent. of the cases showed chronic changes in the kidneys. Tuberculosis of the kidneys was observed in 58 per cent., or about two-thirds of the cases in which the kidneys were affected. In the other one-third, the cases were due exclusively to the excessive amount of toxins which the kidneys were compelled to eliminate. The fact that the majority of patients in whom diseases of the kidneys occur are not subjects of tuberculosis affords sufficient evidence that other toxins besides those produced by the tubercle bacillus may be important factors in the production of this condition. That renal disease, both acute and chronic, may result from the absorption of toxins originating from putrefaction in the alimentary canal is no longer doubted. The renal lesions present in various intestinal infections are sufficient evidence of this.

In the face of such facts it would seem to be quite unnecessary to urge the necessity of exercising every possible care to avoid excessively taxing the kidneys, not only by suppressing irritating condiments, the need of which is recognized, but by avoiding any unnecessary increase of nitrogenized wastes, of which the kidney is the chief outlet. A ration furnishing 410 calories, or 100 grams, of protein will demand of the kidneys less than one-third as much work as a dietary supplying 1,200 calories or 300 grams of protein.

In the face of these facts it seems proper to raise the question whether the feeding of large quantities of protein in tuberculosis may not aggravate one of the most grave and incurable of the lesions incident to this malady. Indeed, it is even proper to inquire whether a high-protein dietary may not be very largely responsible for the great number of cases of renal disease observed as a complication of pulmonary tuberculosis. Certainly it cannot be denied, in the face of such evidence as this, that the kidneys must be considered when arranging the bill of fare of the patient suffering from phthisis pulmonalis.

Every modern author on the dietetic treatment of renal disease insists that the amount of work required of the kidneys must be diminished as much as possible, and that hence the proportion of protein should be reduced, and the extractive matters of meats should be especially avoided, and even that the amount of sodium chloride should be reduced

to the minimum. Hutchison urges that flesh foods should be allowed only in very small quantity in renal disease, and advises that the proteins should be "derived largely from vegetable sources." Freidenwald and Ruhrah entirely prohibit strong meat broths and beef teas, and reduce the protein to 30 or 40 grams. They also limit the chloride of sodium and state that "meat should be used cautiously." In chronic interstitial nephritis they advise that the protein ration should be reduced as low as 60 grams.

Hirschfeld emphasized the inability of the diseased kidney to eliminate nitrogen. The diseased kidney is like an obstructed filter. With a diet of 70 grams of albumin a healthy kidney eliminates 10.1 grams of nitrogen, the diseased kidney 9.3 grams. When the albumin ration is increased to 130 grams, the healthy kidney eliminates 14.5 grams, and the diseased kidney only 11.7 grams. When the ration of 130 grams is continued for a few days, the disproportion increases, the diseased kidney eliminating only 12.7 grams, while the healthy kidney eliminates 18.6 grams. Thus the diseased kidney under a ration furnishing 533 calories of protein—considerably less than the amount often given consumptives—is able to eliminate only two-thirds of the nitrogen intake.

It is evident, then, that the consumptive patient who is fed on a high protein diet is thereby not only rendered more liable to fatal hepatic and renal complications, but through the accumulation of the retained products of protein metabolism, all his functions are hindered, and all his tissues are exposed to a damaging influence.

Gautier emphasizes the necessity of reducing, in renal disease, "the toxins and other offensive products to the minimum by diminishing the consumption of the food principle from which they originate (protein). He permits meat in small quantities, 20 grams of protein, and recommends especially bread and cereals, cereal soups, purées of vegetables, potatoes, rice, and all fruits, giving as the reason that "these foods do not produce, or only in very small quantity, urinary toxins." W. Gilman Thompson says, "Whatever views may be entertained in regard to the causation of albuminuria, it is agreed by all that cooked meats, eggs, and highly seasoned foods in general are injurious in all cases." Senator, of Berlin, in cases of serious renal disease, prefers to prescribe only vegetables, salads, fruits, or an exclusive milk diet of two liters per diem. It seems a just conclusion from the facts presented in this paper that the recommendations made in relation to diet in renal disease are equally applicable to the average cases of pulmonary tuberculosis.

If a high protein ration in general is open to suspicion in tuberculosis, a flesh diet is particularly questionable for several reasons:

1. Flesh proteins more readily undergo putrefactive decomposition than do vegetable proteins.

2. Flesh foods as eaten always contain, ready formed, a considerable amount of toxins which have resulted from putrefactive processes which take place in the flesh after killing, while being "ripened" in preparation for the market.

3. Flesh foods always contain multitudes of putrefactive bacteria in active growth, and hence introduce into the intestine an agent in the highest degree calculated to encourage intestinal autointoxication and to aggravate some of the gravest features of the disease. In the early stages of the disease in which hyperhydrochloria frequently exists, the putrefactive bacteria contained in the infected meat may be destroyed by the free hydrochloric acid present; but later on in the disease, when free hydrochloric acid disappears from the gastric secretion, this germicidal action is lost and the billions of putrefactive bacteria which may be swallowed at a single meal pass on into the intestine where they may be able to develop without hindrance, aggravating the toxemia which is produced by the disease itself, thus rendering futile efforts which might otherwise succeed in arresting the disease, and so hastening the patient's demise.

The following table gives the results of careful bacteriological studies made in our clinical research laboratory by Dr. A. W. Nelson:

TABLE VIII

	Specimen	Putrefactive Bacteria Per Gram of Meat	
		When Purchased	After 20 Hours at Room Temp.
No. 1	Large sausage	420,000,000	490,000,000
" 2	Small sausage	663,000,000	640,400,000
" 3	Round steak	560,000,000	840,000,000
" 4	Roast beef	560,000,000	750,000,000
" 5	Smoked ham	43,120,000	[illegible]
" 6	Hamburger steak	129,000,000	[illegible]
" 7	Pork	126,840,000	[illegible]
" 8	Porterhouse steak	30,000,000	[illegible]
" 9	Sirloin steak	578,000,000	[illegible]
" 10	Tenderloin (well done)	25,200,000	[illegible]
" 11	" (rare)	168,000,000	[illegible]

It would seem idle to pay so great attention to the reduction of the bacteria in milk while consuming daily in such enormous quantities bacteria of a much more noxious character. The bacteria of milk are for the most part aërobes which form harmless acids, while the putrid bacteria which abound in meat are toxin formers and capable of establishing themselves in the intestines and continuing to thrive there at the expense of undigested proteins. It is apparent, then, that a double injury must result from the ingestion of large quantities of flesh foods. There is not only introduced a surplus of protein which cannot be utilized, and which is allowed to undergo putrefaction, but along with the protein are introduced putrefactive organisms already in a state of active growth.

While the writer is not a specialist in the treatment of pulmonary tuberculosis, he has during the last thirty-two years had constantly cases of this sort under his care, and has had considerable opportunity to observe the clinical effects of both a low-protein and a high-protein dietary. Without burdening this paper with reports or with elaborate statistics, it may be stated that a very considerable number of patients have been seen to make good recoveries from well pronounced tuberculous disease of the lungs on a dietary which furnished not more than 300 calories of protein in the form of eggs, milk, and vegetable protein, and often less. On the other hand, there has frequently been a rise of temperature and an aggravation of other symptoms when a digression was made to a diet of flesh foods such as beefsteak, etc. Several times patients have come under our care who had been subjected to forced feeding with disastrous results. The enthusiastic advocacy of forced feeding by Débove, Broca, and Dujardin-Beaumetz, and the slavish way in which for a time the example of these clinicians was followed, has led in not a few instances to most disastrous results. The chief evils of these large dietaries doubtless result from the excess of protein and fats. The excess of protein encourages intestinal decomposition as do also the fats, while fats

inhibit the gastric secretion of hydrochloric acid and thus interfere with both the digestion and the disinfection of the excess of proteins, and so still further promote intestinal autointoxication. Lawrason Brown, in Osler's "Modern Medicine," especially warns against an excess of proteins.

Bardswell and Chapman found that "patients make much less satisfactory progress on the very large diets than on diets of considerably smaller nutritive value." The same investigators observed that "any considerable increase in the protein in the diet produced a disproportionate excretion of nitrogen, an increase in the amount of imperfectly oxidized proteins in the urine, a decrease in the percentage of nitrogen absorbed, and an increase in the amount of aromatic sulphates excreted, indicating increased intestinal putrefaction." These authors conclude that the most satisfactory diet for the consumptive "is one which represents only a moderate increase of a diet suitable for him in ordinary health." They recommend a diet consisting of "120 grams of protein, 180 grams of fat, 300 grams of carbohydrates." A smaller amount of protein will still further diminish the intestinal putrefactions, and the writer believes will secure even better results. Advantage will be found in employing vegetable proteins instead of animal proteins, because of their more ready digestibility when presented in the proper form, their absolute freedom from bacteria, and the less readiness with which they undergo putrefaction. Wheat glutens and the vegetable proteins of peas, beans, lentils, and nuts, are readily available, and when properly served are easily digested and readily absorbed.

Dr. Lawrason Brown notes in his admirable article on the treatment of tuberculosis in Osler's "Modern Medicine" that the method of forced alimentation rarely yields permanent success, and also warns against the use of foods which are likely "to give rise to toxic action of the liver and kidneys." If meats are not to be included in the class of foods which "encourage toxic effects upon the liver and kidneys" and hence must be avoided, unusual care must be taken in their preparation. The meat should be cooked as quickly as possible after the animal is killed, and should be eaten within a day or two unless kept at freezing temperature. In no other way can the putrefactive processes which begin almost immediately after death be prevented. The ordinary cooking temperature does not destroy the spore-bearing bacteria. The temperature of the interior of a portion of meat seldom reaches the boiling point during cooking. A meat diet invariably increases intestinal autointoxication.

As regards plant proteins and flesh proteins, my observation has been that consumptives, when taking a non-flesh dietary, frequently experience an elevation of temperature and an aggravation of symptoms on changing to a mixed diet.

At the time of this writing I have under my care a patient who was recently discharged from an excellent sanatorium where he was apparently cured of pulmonary tuberculosis, but is suffering very seriously from intestinal autointoxication as the result of a high-protein flesh diet. He is rapidly improving under a low-protein dietary.

Mr. Horace Fletcher and others have shown the essential importance of thorough mastication, not only as a means of securing good digestion and assimilation of food, but as a means of regulating the proportion of food principles. The effect of thorough chewing or Fletcherizing of the food is, in general, to reduce the amount of protein ingested. This seems to be the natural result of giving the gustatory nerves a chance to act in conjunction with the psychic centers which are associated with the digestive process. The nerves of taste seem to be an admirably accurate regulator of nutrition in health, and not infrequently in diseased conditions the suggestions of this ever alert monitor cannot be with safety altogether ignored. If the appetite craves protein, then protein is doubtless needed to satisfy the body needs.

The main facts presented in this paper may be briefly summarized as follows:

1. A low protein dietary, .80 to 1.00 gram of albumin per kilogram of body weight per diem, is entirely consistent with health, vigor, and a high degree of efficiency and endurance in health.

2. While a patient suffering from pulmonary tuberculosis doubtless requires a small increase in the intake of nitrogen, an excessive increase involves grave dangers to the patient, both (*a*) by decreasing his general vital resistance, and (*b*) by imposing unnecessary and dangerous burdens upon the liver, kidneys, thyroid, and other organs which are already overburdened and often seriously crippled in this disease.

3. There is no evidence that a larger proportion of consumptives recover under a high protein diet than under a protein ration sufficiently above the Chittenden standard to replace the nitrogen loss due to febrile conditions in certain states of the disease.

4. The majority of consumptives die from disease of the liver and kidneys. The toxins peculiar to this malady and to the process of immunization against tuberculous disease, while tending to cure the latter, tend at the same time to produce disease of the kidneys, and to such a degree that patients not infrequently die of renal disease after having apparently recovered from tuberculous disease.

5. In consumption the organism is required to deal with various highly virulent poisons which overstimulate and ultimately cripple or destroy the thyroid, adrenals, liver, and other antitoxic organs. A high protein diet produces similar effects in healthy animals and persons, and destroys life in animals whose poison-destroying functions are seriously impaired.

6. A high protein diet is recognized as an important factor in the causation of renal disease and is universally condemned in grave affections of the liver and kidneys. Vegetable proteins are much less objectionable than flesh proteins for the reason that they are entirely free from toxins and very much less readily undergo putrefactive changes in the intestine.

It readily appears to the writer that the logical and inevitable conclusion from these facts is that a high protein dietary is not only unnecessary but injurious, and even dangerous, in the treatment of phthisis pulmonalis, and that vegetable proteins may be with advantage largely substituted for flesh proteins in the dietetic management of this malady.

CHOLECYSTECTOMY VS. CHOLECYSTOTOMY.*

By JOHN F. ERDMANN, M.D.,

NEW YORK,

PROFESSOR OF SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

An article by me, titled "Cholecystectomy: With a report of twenty-seven cases," was published in the *New York Medical Journal*, February 24, 1906, from which the following is taken: "That one can exist without a functionating gall-bladder is a well known fact, proved many times by the autopsy and operating-table findings. In many gall-bladders the cystic duct is occluded by stone, exudate, kink, etc., so that the storehouse function of this viscus has not been carried on for months or years. Given this as a fact when one has a case of cholecystitis, or disease of the gall-bladder in which time as a curative agent cannot be relied upon, or when the condition is a menace to life, our judgment should demand the removal of this organ. Cholecystectomy has been, and is yet considered by many, an operation of choice only when marked gangrene, or malignancy of the bladder is present."

The following indications and contraindications for cholecystectomy were included in the same article: "Indications: Perforations by trauma; ulceration other than due to abscess or gangrene (see case of typhoidal perforation); obliteration, or stricture of the cystic duct; chronic cholecystitis with thickened walls; atrophy; gangrene; acute suppuration; enlargement by dilatation; these latter are usually due to either calculus obstructions, strictures or angulations of the gall-bladder, etc.; marked adhesions; hourglass contractions; chronic or recurring cholecystitis, or cholelithiasis and malignancy."

*Read before the Academy of Medicine, November 5, 1908.

"Contraindications: Apparently healthy bladder in cholelithiasis and pericholecystitis; perforations into other viscera, when difficulty of closure of the anastomosis is great; perforations in the suppurative variety when adhesions are extensive, and where life would be jeopardized by such radical interference; malignancy when extensive, and those cases where hurried operation is indicated to save life."

While adhering to these views in the main I am not so radical now, and consider the cases more closely before performing cholecystectomy. The reasons for this change are, one, a distinctly surgical one of convenience, that occasionally one must do a secondary operation upon the common duct, either for an overlooked stone or for a stone that has been concealed or formed in the liver which comes down, necessitating either a choledochotomy or leaving the patient a chronic invalid in case the stone does not pass. When such secondary operation is called for one has lost, in the absence of the bladder, the anatomical landmark to the duct, and we are compelled to do the most tedious and delicate adhesion dissection work conceivable. Upon two occasions this lot fell to me in cases that I personally had operated upon, in both of which it is but fair to say that cholecystectomy was done for gangrene, one in a girl of seventeen in whom I practiced hepatic lavage, when numerous small stones and much sandy material was ejected from the hepatic ducts with each washing, and in which instances the prospect of secondary work was predicted. The other was a male patient with a badly infected gall-bladder, enormously enlarged, thickened, and filled with stones, in whom we palpated the common duct with unusual diligence. Both myself and my associate felt that none were present in the duct, but some eight or ten months later colic was again in evidence, and about eighteen months later a secondary operation, choledochotomy, was done, removing a stone three-quarters of an inch long by fully one-quarter inch wide. The inconvenience and hazard of this operation can only be appreciated by a like experience at the hands of any operator.

Another reason is that occasionally, when necessary to do a secondary operation upon other of the abdominal viscera or a secondary operation upon the duct, it has been observed that a pseudo gall-bladder is formed by a dilatation or diverticulum formation of the duct, disproving to a degree that we can all do without our gall-bladders or allied storehouses, for the excess of bile formed during intervals of digestion.

Fortunately so far I cannot reproach myself for secondary work upon any case of cholecystectomy upon a slightly thickened, etc., gall-bladder of the variety that I am now prone to do a cholecystotomy upon. Cholecystotomy also has its secondary operative aspects, and these are, the possibilities of reinfection without stone, or the reformation of stone. I can also say here that, fortunately, so far I have had to do no secondary work upon cases of cholecystotomy done by me, although such cases may have gone to other operators, as one has recently come to me after an operation by another surgeon.

The question of cholesystectomy and cholecystotomy very naturally arises chiefly in the cases of acute cholecystitis, and in a certain percentage only of chronic gall-bladder cases, where upon opening the abdomen the gall-bladder is found atrophied or contracted, thickened with or without calcareous

degeneration, and when the cystic duct, by whatever means, has been occluded, resulting in a hydrops of the gall-bladder, while in cases of malignancy the question is, cholecystectomy, etc., or closure of the abdomen without interference.

In the acute cases that I see the first consideration is for the patient's recovery from the operation. Should his condition be one that demands a rapid operation, and the bladder is gangrenous, I feel that a few minutes more of operative procedure will justify a cholecystectomy, as the danger of infection, sloughing, and hemorrhage is removed with a smaller risk than is taken by leaving the diseased viscus for the above possibilities, added to those of a second operation when the patient is apparently healthy.

Should the condition be grave, and only a thickened gall-bladder with infection be present, the removal of the bladder contents only is done; this latter step, of course, including necessary cystic and common-duct work if called for.

Where no great consideration of time and shock as a factor arises I do a cholecystectomy if the bladder wall is friable, very thick, the bladder markedly elongated and thick, spot patches of gangrene or grayish white slough seen quite frequently in numbers of my cases, partial, *i. e.* a large area of gangrene, or complete gangrenous destruction. Also if upon opening the gall-bladder isolated areas of the entire field of mucous membrane be gangrenous. In these cases if cholecystectomy is not done a fair hypothesis of subsequent adhesive exclusion of the gall-bladder can be advanced. I do not feel, with one of our mid-western operators, that cholecystectomy is not advisable in these cases, he stating at one of his clinical lectures that his custom was to keep the gall-bladder open for weeks, using an endoscope frequently, to see the healthy granulations springing up in the bladder, and that safe closure could take place as soon as such healthy granulations had covered over all former necrotic areas."

Evidence of calcareous degeneration in an acute cholecystitis also calls for a cholecystectomy. This condition was encountered twice in my series.

Acute cholecystitis in cases of old contracted gall-bladders demand cholecystectomy, as they are simply old smoldering foci for repeated attacks, and a cholecystotomy in these cases is of no more than a temporary benefit. Cases where the gall-bladder is acutely inflamed, and the bladder distended, the walls not over thick nor infiltrated, with no mucous membrane destruction by gangrene or ulceration, I am now prone to drain.

Ulceration perforations of the gall-bladder, such as occasionally occur in typhoid, etc., and gunshot, and other wounds with great laceration, should have the radical operation done instead of attempts at closure, as in these cases the danger of leakage, tearing out of sutures, etc., is greater than in the now discarded cholecystendese, or ideal cholecystotomy.

Malignancy. Finesse of judgment as to to our procedure in these cases can be obtained only by experience. Shall we do a cholecystectomy, or close the abdomen, leaving the patient his sure and inevitable death by this disease?

Four cases of malignancy were seen by me. One opened and closed, died within six weeks. One with a partial removal, accidental, died in four days. One with a cholecystotomy, also accidental, while attempting to orient myself, died in three days. The other, a cholecystectomy for gangrene with a profound malignant invasion of the common duct, drainage of the hepatic being done, died in three days, death being due to uraemia. No anastomosis was possible here, as we had a carcinosis extending into the hepatic duct just above its junction with the cystic. The drainage into the hepatic was made with a view of relieving the patient of a cholemia and intense jaundice, in hopes that some subsequent device or treatment could be used for the biliary leakage.

As a result of these four cases, although a small number for a conclusive argument, I shall be inclined to close the abdomen in every case, except in those of the slightest invasion, and even then in those cases only where the growth removal would be accompanied with the sense of completeness justifying a prognosis of relatively little danger of return.

Cases operated upon. In twenty-six cholecystotomies out of a hundred and four operative cases of all kinds considered in this paper one case is recorded of death due to a malignancy.

There were fifty-three cholecystectomies, with three deaths; one a malignancy; one a case of four previous operations by other surgeons, the fifth being done by myself, including drainage for multiple abscess of the liver; and the third due to gastro-mesenteric ileus.

Excluding the malignancies in both operative procedures and the case of multiple abscess, in all of which a mortality was inevitable, we have a record of twenty-five cholecystotomies with no deaths, and fifty-one cholecystectomies with one death, or less than two per cent. These fifty-one cases included associated appendectomies, subphrenic abscesses, two pregancies and one post-partum in the second week, making a decidedly complicated set of operations.

There was one case of cholecystotomy with choledochotomy, with recovery. There were twenty cholecystectomies with choledochotomies with five deaths, one a malignancy, leaving nineteen cases with four deaths. One of these died of inanition after the eighth day. This patient was suffering from exhaustion and inanition, due to a large number of stones in her gall-bladder and common duct. Her post-operative condition was perfect except for the fact of a progressive exhaustion.

A third death in this series was a male patient, fifty-three, with marked obstructive jaundice; comatose at the time of the operation; death from anuria. The fourth death in this series was also due to anuria, the patient passing but twelve drachms of urine in twenty-six hours.

Choledochotomy was done in four cases; no deaths. This series of cases therefore, by excluding three malignancies and one of multiple hepatic abscess, consists of one hundred cases operated upon, with seven deaths, none of which occurred in twenty-five cholecystotomies, and only one in fifty-one cholecystectomies. The difference here is of really no value as a factor for consideration of the choice of cholecystotomy, as it must be remembered that the majority of the cholecystectomies were serious cases; acute, gangrenous, and complicated with other conditions, two pregnancies and one post-partum (?) in the second week, two with hysterectomies (both recovered); etc., etc., while the cholecystotomies were done in practically each instance in a relatively clean case.

A summary of the cases of cholecystotomy and cholecystectomy with those in which additional duct work was done will show that out of the hundred

considered, excluding the malignancies and the one of multiple abscess of the liver, cholecystotomy was done twenty-five times, cholecystotomy with choledochotomy once, making twenty-six cases without a death. Cholecystectomy was done fifty-one times with one death, and cholecystectomy with choledochotomy nineteen times with four deaths, a total of seventy cases with five deaths.

THE DIAGNOSTIC USE OF TUBERCULIN WITH SPECIAL REFERENCE TO THE CUTANEOUS AND PERCUTANEOUS TESTS.*

By HENRY FARNUM STOLL, M.D.,

HARTFORD, CONN.

PHYSICIAN-IN-CHIEF, CLINIC FOR PULMONARY TUBERCULOSIS, HARTFORD DISPENSARY; ASSISTANT PHYSICIAN TO HARTFORD HOSPITAL.

That tuberculin is a safe and valuable aid to diagnosis is not appreciated by the profession at large. There exists in the minds of many a natural aversion to the use of a substance made from tubercle bacilli. Some, remembering the disastrous results which followed its early therapeutic use, before the correct dosage has been determined, consider it a distinctly dangerous substance, capable of lighting up an old inactive lesion, or of increasing an already active one. Others fear that possibly tuberculosis might be given to one free from the disease.

That large doses of tuberculin, given indiscriminately, will do harm no one denies. Of course, if one give a patient with Addison's disease an initial dose of 7 mg., as has recently been reported, the patient will die; and so he would were he to receive a grain or two of strychnine. But that a small amount in proper cases is harmful, is refuted by Trudeau, Osler, Cornet, Koch, and a host of others who have had a wide experience with it; Koch alone reporting 3,000 tests with "no disadvantageous results."

The fear that tuberculin might cause tuberculosis is due to a misunderstanding as to what the tuberculin used for diagnosis consists. This particular variety, known as old tuberculin (T. O.), is the glycerin extract made from cultures of human bacilli which have been evaporated by heat to 1/10 their original volume. These dead bacilli are then removed by filtration and the filtrate is the part used. Wolf-Eisner is of the opinion that the action of tuberculin is due to the presence of the bodies of bacilli, either whole or in fragments, which pass through the filter. Lysin substances present in the tuberculous individual liberate the toxins from the fragments of the baccili, causing a tuberculin reaction. Hamburger[1] has demonstrated that large amounts have no untoward effect on individuals free from tuberculosis. He injected forty-three children who were negative to the skin test, with amounts of old tuberculin varying from 10 mg. to 100 mg., and in no case was the slightest general reaction obtained. One girl of six years received as much as 500 mg.

The methods of administration are the subcutaneous, cutaneous, percutaneous, and conjunctival. Until recently the first has been the one most used. In using the subcutaneous test I proceed as follows: After the temperature has been taken for a week and found to be below 100° (mouth), an initial dose of less than 1 mg.—usually .25 to .5 mg.—is given about [illegible]. In very nervous it is well to give an injection of saline solution the day previous to the test. On the morning following the tuberculin injection the temperature is taken at 6 o'clock and every two hours thereafter for the next forty hours, unless a reaction develops before.

A typical reaction coming on in a little from twelve to twenty-four hours, consists of headache, malaise, pains in the limbs, and sometimes nausea and vomiting. A rise of temperature of 2 degrees or more almost always accompanies the general reaction, and a certain amount of local reaction, consisting of redness, swelling, and tenderness, is regularly present at the site of injection. A local reaction in the lung, consisting of an increase of râles, or their appearance where previously absent, occurs in some cases and proves the case to be

Cutaneous Test of von Pirquet, showing three degrees of early reactions. "a" is a moderate reaction, "b" "strong reaction" and "c" "very strong." All were children in their early teens. a and c were not clinically tuberculous; b had an enlarged cervical gland considered tuberculous.

tuberculosis. This local reaction in the lung not only is harmless, but sometimes appears to be beneficial.

No reaction resulting from the first dose, 1, 3, 5, 7, and 10 mg. may be given at intervals of three or four days, though the clinical import of a reaction from 7 to 10 mg. is much less than that obtained from a smaller dose. When the reaction from the first dose is indefinite, the repetition of the dose will frequently give a positive result. The disadvantages of this method are (1) it is not applicable to fever cases; (2) a week or more is sometimes required to complete the test; (3) the patient feels miserable for a day or two; (4) it requires the frequent taking of the temperature.

The contraindications, as given by Brown, are a temperature of 100°, extensive physical signs, great dyspnea, hemoptysis within a month; general glandular involvement, meningitis, kidney and heart disease and epilepsy.

*Read at the semi-annual meeting of the Hartford County Medical Society, held in Hartford October 27, 1908.

The Conjunctival Test.—This was devised independently by Wolff-Eisner and Calmette. It consists in the sensitiveness of the conjunctival mucous membrane of tuberculous individuals to the instillation of tuberculin into the eye. A 1 per cent solution of old tuberculin freshly made with physiological salt solution has been found to be as satisfactory as the more difficultly made preparation used by Calmette. In about 87 per cent of the cases of clinical tuberculosis, and in 15 per cent of non-suspects, injection of conjunctiva occurs within twenty-four hours. It is usually more marked on the palpebral than on the ocular conjunctiva, though both may be deeply injected when the reaction is severe. In the latter type of reactions a seropurulent discharge is present and itching and photophobia are complained of. Occasionally a mild general reaction is met with. Calmette[2] reports 6,303 tests with three cases of keratitis resulting, also 20 of conjunctivitis, and a prolonged reaction lasting beyond three weeks in 72 cases, but "no grave disturbance or permanent ocular lesions." Wolff-Eisner[3] is highly satisfied after using it in 2,500 cases. In 1,087 tests Baldwin[4] reports keratitis occurring once in a scrofulous patient and a reaction lasting over 5 days in 10 cases.

In 28 tests I have had one sharp reaction lasting over 10 days as the result of using the second solution in the other eye at the end of 24 hours rather than at the expiration of 48 hours. No harm resulted in this case, but a mild recurrence of the reaction was noted a year later following the subcutaneous injection of .0000005 of bouillon filtré (Denys' tuberculin). A number of cases have been reported, however, where serious lesions resulting in impairment of vision have occurred. Some of these cases were due to its employment where it was clearly contraindicated, and in certain others mistakes have been made in the dilutions. Thus one German firm is reported having marketed a 10 per cent. solution labeled 1 per cent.[5]

There are, nevertheless, a sufficient number of cases on record where its apparent careful use resulted disastrously, to make one use the test with considerable hesitation. Then, too, Baldwin concludes that it is of "little value where the symptoms of tuberculosis lead only to a suspicion." I have given up the test for the above reasons and because the cutaneous test, as now used, seems to be of about as much value. The conjunctival test should never be used in scrofulous patients or where a conjunctivitis or iritis exists, or has existed.

Cutaneous Test.—This was devised by von Pirquet and in contradistinction to the conjunctival test is absolutely harmless. On the other hand, healed lesions react to it much oftener than to the latter. Yet the percentage of reactions is not much higher than is obtained from large doses used subcutaneously. Franz found that 60 per cent. of apparently healthy army recruits reacted to the subcutaneous test. Madison found that 40 per cent. of 400 women insane patients reacted to 10 mg. or less. Von Pirquet at first employed a 25 per cent. solution of old tuberculin, but more recently he has been using it undiluted. The test as given by v. Pirquet is as follows: The flexor surface of the forearm is cleaned with ether and two drops of tuberculin are placed thereon, about three inches apart. The skin is drawn tight by grasping the arm from underneath with the left hand. A scarification is then made midway between the drops, and next in the center of each drop. The excess of tuberculin is removed with absorbent cotton. Nothing is placed on the control. Pirquet estimates that about 1/100 mg. is absorbed. The scarification is best done with a small, rather dull chisel-shaped instrument, which, when rapidly revolved between the thumb and finger, makes a cup-shaped abrasion about 1 mm. in diameter. While a needle may be used as in ordinary vaccination, the special scarifier is to be preferred as the resulting papule is circular in outline, and accordingly easier to measure. The most satisfactory results are obtained when the instrument is revolving rapidly at the moment it comes in contact with the skin. The resulting abrasion is slight and should not be deep enough to draw blood. Usually at the end of twenty-four hours, if the reaction is positive, a red papule appears at the point of vaccination. A mild reaction looks considerably like a mosquito bite with a small central depression. In a few of my cases the papule was surrounded by a hyperemic area several millimeters in diameter. In these cases the papule was elevated, glassy, and hard, presenting a crater-like appearance. In two cases a few very small vesicles were present in the hyperemic area. This is shown on the middle arm in the accompanying illustration, which is the arm of a boy with a large cervical gland. A slight constitutional reaction was present in this case. Reactions occurring by the end of twenty-four hours v. Pirquet calls "early reactions," and considers that the infection has taken place in later years. Those appearing after this he designates as the "late reactions." He has noted that in most of the clinically tuberculous with good "reactivity," the papule reaches considerable size by the end of twenty-four hours, being from 12 to 15 mm. in diameter. The maximum size is generally reached on the second day. In "larval" tuberculosis the diameter is apt to be somewhat less. In healed tuberculosis the papule may not appear until the third or fourth day, or not at all unless the patient is revaccinated a week later. When time is an object, this delay of a week can be avoided by Hamburger's method, which consists in the subcutaneous injection of 1 mg., when the skin test is negative at the end of twenty-four hours. No reaction taking place at the site of injection by the day following, tuberculosis can be excluded. A local reaction, when slight, is best detected by pinching up the skin between the thumb and finger and comparing it with the adjacent skin. It is said that a constitutional reaction never follows the subcutaneous use of 1 mg. in cases in which the cutaneous test has been found to be negative.

Advanced cases react slightly or not at all. The reaction in this class of cases may be very faint, early in appearance, and quickly subsiding. The finger can sometimes detect a reaction that is not visible. These evanescent reactions are a grave prognostic sign, while conversely the late-appearing and persistent ones are regarded by Wolff-Eisner as an indication of a healed lesion. The degree of the reaction is a measure of the patient's resistance, and a strong early persisting reaction indicates "the possibility of victory." It has nothing to do with the amount of lung involved and a slight, quickly disappearing reaction, even though the amount of lung involved is small, is regarded by Wolf-Eisner as a bad omen. He has seen several such cases in which the disease steadily progressed. The strongest reactions were in non-suspects.

My experience with the cutaneous test comprises its use in 300 cases, divided as follows:

TABLE 1.—COMPARISON OF THE RESULTS OF THE CUTANEOUS AND PERCUTANEOUS METHODS.

	Cutaneous (Pirquet)		Percutaneous (Moro)	
	No.	Percent positive	No.	Percent positive
1. Clinical Tuberculosis, all forms	47	87	34	71
Pulmonary, Stage I	6	100	13	77
" Stage II	12	100	5	60
" Stage III	9	44	8	25
Tuberculous, glands	3	100	5	80
" bones	6	100	5	80
" peritoneum	1	100	1	100
2. Tuberculosis suspected	22	72	28	61
3. a Tuberculosis not suspected, and no history of infection in the past	220	29	38	11
b Tuberculosis not suspected, but past history suggests previous infection	13	100	14	43
a and b together	233	34	52	25
4. Native Filipinos	8	75		

TABLE 2.—CLINICALLY NEW TUBERCULOSIS CASES CLASSIFIED ACCORDING TO AGE.

Number	Age	Percent. positive
10	0 to 2	0
41	3 to 5	17
143	3 to 10	33
44	11 to 15	25
*41	16 upward	20

*These 41 include classes *a* and *b* above. Excluding *b* the percentage is 40. Wolf-Eisner obtained positive reactions in 50 per cent. of non-suspects.

Von Pirquet found that children of two years and under do not react unless clinically tuberculous, but that after two years the percentage rapidly increases until at ten it reaches 70 per cent. This agrees with Comby's autopsy statistics for the corresponding ages, which gives a percentage of 65 at the tenth year. Pirquet thinks that a lower percentage probably prevails elsewhere, as the hygienic conditions of the poor in Vienna are very bad. Had it been possible for me to have revaccinated all my negative cases my percentage of positive reaction would probably have been slightly higher.

A large part of the material for this investigation was very kindly furnished me by Drs. Lampson, Simpson, and Wilson, from the Orphans' Home, the Newington Home for Incurable Children, and from the Deaf and Dumb Asylum. A few kindergarten children were tested through the courtesy of Miss Giddings. The remainder were private and dispensary patients.

Eight full-blooded Filipinos, Igorote tribe, who had been on exhibition in England and America for eight months were tested and six reacted. This was a surprise, as they seemed to be in perfect health, and their life in the open air seemed ideal. Investigation showed, however, that they are inveterate smokers of cigar butts picked from the ground, or handed them by visitors. Then, too, they sleep in huts which are kept tightly shut to keep out evil spirits, and though they wear only a breech cloth while on exhibition, at other times they dress comfortably. Two showed some retraction at the apices.

About 100 individuals were tested with 5, 10, and 100 per cent. tuberculin with the view of ascertaining the minimum per cent. to which active and healed lesions would respectively react. In general, old lesions do not react to 10 per cent., and most with active trouble react to 2 per cent. or 5 per cent. This is not absolute, however. Pirquet states that it is not necessary to use different strengths, as much information can be obtained from measuring the diameter of the papule. This was done in about two-thirds of my cases and the procedure seems of value. Of the clinically non-tuberculous who reacted, the papule rarely reached 15 mm. at the end of twenty-four hours, but in 10 per cent. (mostly children), it attained that size by the second day. Of the children who reacted, a number had unhealthy tonsils or adenoids, some looked frail and many looked perfectly well. In fact, one of the most marked reactions occurred in an adult seemingly in the best of health, who had had a very slight cough for two weeks. This demonstrates that a positive reaction without symptoms does not constitute clinical tuberculosis, and that in adults a negative reaction is of more significance than a positive one.

An opinion as to the probable import of a reaction should never be given until a careful history has been obtained and a thorough physical examination made.

If there is nothing in the past history pointing to a previous tuberculous infection of any sort, and the patient has symptoms suggestive of tuberculosis, a strong "early" reaction makes the diagnosis of tuberculosis extremely probable. While a history of previous tuberculous disease increases the probability of the present trouble being tuberculous, it also lessens the significance of a positive reaction *per se*. This is conclusively shown by the 100 per cent. of positive reactions in thirteen such cases. One cannot, however, exclude tuberculosis simply because the papule is small. On scaly skins it is apt to be considerably less than 15 mm. When one is in doubt as to the meaning of a mild reaction the subcutaneous test should be used.

In bone disease and cervical adenitis tuberculin should be used much more than it is. The local reaction in the bone or gland, as the case may be, following the subcutaneous test settles all doubt.

Percutaneous Test.—Several modifications of the Pirquet test have been suggested. Lignières rubs in several drops of tuberculin over an area of skin previously shaved and cleaned. Moro uses an ointment of equal parts old tuberculin and anhydrous lanolin. A piece about the size of a pea is rubbed in over an area of 4 square inches. If the reaction is positive, small papule appear within from twenty-four to forty-eight hours over the area anointed and adjacent thereunto. The reaction has even been observed over the corresponding side of the body, which leads Moro to believe that it is a vasomotor phenomenon. The papules vary in number from two or three to fifty or more and may be pale and indistinct or bright red with some vesiculation. They as a rule dry up within two weeks. Itching is present when the reaction is strong. Moro considers it as valuable in children as the Pirquet test and more valuable in adults, as fewer non-suspects react.

I have observed it in 107 cases, controlling it in 61 with the cutaneous test. The results can be seen in Table No. 1.

Moro's contention that non-suspects react less often to his test than to the cutaneous is borne out by my experience, the percentage with the former being about that obtained with the conjunctival test. One infant suspected of having general tuberculosis gave no cutaneous reaction to two tests, but each time had a rise of temperature of over 102—as the child has steadily improved the condition was probably marasmus rather than tuberculosis. It would seem that the dosage by this method must vary widely, depending upon the power of absorption through the skin, the amount of ointment used, and the thoroughness with which it is rubbed in. Pulmonary tuberculosis does not react as readily

as other forms and for that reason, possibly, Moro has recently advocated using 5 c.c. of tuberculin to 4 gm. of lanolin. The 13 first-stage cases given this test were mostly "pretuberculous" and a few might perhaps have been classed with "suspected cases." Only 60 per cent. of the second-stage cases reacted, while with the cutaneous test all was positive. The Moro test does not appear to be reliable in adults with pulmonary tuberculosis, but in children, especially in bone and gland disease, it seems about equal to the v. Pirquet test. Its disadvantages are that it takes longer to administer, and does not appear to afford as much help in differentiating between an active and inactive process as the cutaneous test when the diameter of the reactionary papule is considered. Some cases which at first give a negative response to the test will react if it be repeated.

Detre's Differential Test.—The author uses a drop each of human and bovine filtrate and old tuberculin. Both human and bovine infections react to the T. O., and when it is a mixed infection both the human and bovine filtrate react. When but one type of bacillus is present Detre asserts that a reaction will occur only at the point innoculated with that variety of virus. Should further investigation substantiate these claims, it would have an immense prophylactic as well as therapeutic value. But inasmuch as Detre does not standardize his filtrates, and has given no reports of autopsies substantiating his claims, the test must be conceded to be still *sub judice*.

The cutaneous test is simple, safe, painless, and quickly performed. The undiluted tuberculin keeps indefinitely and is conveniently dropped from a dropping bottle. The ointment will keep for months if in a cool place. We now have a means of detecting tuberculosis in children of two years and under which practically never fails. My experience demonstrates its practicability and value in institutions, kindergartens, schools, and dispensaries as well as in private practice. One hundred children can be given the test in an hour. Children who react should be examined for enlarged tonsils, adenoids, and enlarged cervical glands. Grancher found that 15 per cent. of over 4,000 school children examined in the Paris schools were tuberculous or strongly suspicious. The school nurse should investigate the home conditions of those who react and usually an open case of tuberculosis will be found. Should the child be frail, but not clinically tuberculous, half a day in school with the rest of the time out of doors, with a plentiful supply of fresh air at night, might be all that would be necessary to make a sturdy youth out of one who in the natural course of events would become a tuberculous invalid.

The cutaneous test is the most important addition to tuberculosis work since the discovery of the bacillus. It has vast statistical value, and when used understandingly will prove a material aid in diagnosis and prognosis.

THE TREATMENT OF ERYSIPELAS BY MEANS OF CARBOLIC ACID AND ALCOHOL.

By ASPINWALL JUDD, M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF SURGERY AND RADIOLOGIST, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

There is probably no disease in the realms of surgery or medicine for which a greater number of remedies has at one time or other been proposed and rejected than for erysipelas; and, as in other diseases where a multiplicity of remedies are offered us, their efficiency is usually in inverse proportion to their number. The use of carbolic acid in the treatment of various inflammatory conditions has been exploited from time to time for a number of years, with a considerable amount of success in individual cases.

About eight years ago we began, in our clinic, to treat all cases of erysipelas by the method to be described, and since the first case so treated, we have seldom failed of a satisfactory result and have discarded all other remedies in the treatment of these cases. Up to the present time our statistics show eighty-two cases treated, with five failures, ten delayed recoveries, and sixty-seven complete remission of symptoms in from twelve hours to four days. These cases have included not only the beginning stages of facial and other forms of erysipelas, but those in the advanced stages, where the area involved has varied from the face only to the face, scalp, and with marked general septemic symptoms.

Almost the first result noticed by the patient is a complete cessation of the unendurable itching, burning, and throbbing. Usually within a few hours the nausea, if such is present, subsides, and within twenty-four hours the temperature sinks to normal, the pulse very rapidly falls in the severe cases from 120 degrees or more to nearly normal, the appetite returns, and, except for the diminished swelling, which remains for twenty-four or forty-eight hours longer, the patient is relieved from his distressing symptoms.

Technique of the Method.—This consists of painting with a swab of cotton the entire surface of the involved area, and extending about a half inch into the surrounding apparently healthy skin, with a 95 per cent. carbolic solution. This is left until the purplish color of the inflamed area is replaced by a pretty complete whitening of the skin. It is essential to the success of the procedure that we await this whitening before we proceed to the next step in the operation. On the other hand, if we allow the whitening to proceed to a thorough blanching, we shall produce a burn and a slough of the skin, which will prove painful to our patient and add nothing to the efficiency. Where we have large areas involved, it is advisable that only a portion be painted at a time. The second step consists in going over the whitened area very thoroughly with a second swab saturated with pure alcohol. If this swabbing is done thoroughly, the whitened area becomes once more pink, and the alcohol must be laid on until this is accomplished. After this we proceed with other areas with the carbolic, neutralizing with alcohol, until our operation is complete. It is essential that we should include a half inch of the apparently sound skin, as the bacteria of erysipelas are found beyond the apparently involved area. In some of our first cases treated we neglected this

precaution, and found in twenty-four hours that, while we had completely controlled the initially inflamed area, a ring of newly inflamed tissue extended out in all directions beyond, much as an advancing ringworm extends. Our method includes the painting of the hairy scalp, the eyelids, the mucous membrane of the alæ of the nose, and the nipple of the breast, if necessary. We have failed to note any evil result from its use. There has been no toxic action of the carbolic in any case so far observed, although the urine is sometimes darkened and of characteristic odor. The temperature rapidly falls, and, in severe cases, it is frequently necessary to support the patient with stimulation of strychnine and whiskey.

In looking over our statistics, it has been interesting to observe that, in the majority of cases of failure, our patients have been young children. These have also been the cases in which we have had the greatest number of symptoms of absorption of carbolic, and we suppose it may be due to the more delicate texture and more rapid absorbing power of the skin in these young patients.

An observation made in one of our earlier cases may prove interesting. This was a recurrent, postoperative case of tuberculous osteomyelitis of the tibia in which erysipelas developed. When I saw this case in consultation, the patient, a girl of thirteen, was suffering from an inflammation involving the entire leg and part of the thigh. The parts were tremendously swollen, patient had a temperature of 106°, was delirious, had had nausea and vomiting, and an imperceptible pulse. I suggested that, as the patient was apparently nearly moribund, it would do no harm to try this treatment, and that we might obtain some benefit. Much to my surprise, the following morning I was called on the telephone by the physician in charge, who informed me that the patient had a subnormal temperature, that the pulse was nearly normal, the child was asking for food, also that he had been stimulating since early in the morning with large doses of whiskey and strychnine. The child made an uninterrupted recovery, and, curiously enough, the area of tuberculous osteomyelitis, which involved nearly two-thirds of the tibia, promptly healed, and the patient has remained well to this day.

Another case showing the fearlessness with which this method may be used occurred in a young woman of social position, very beautiful, of the thin-skinned, blonde type. When I first saw the patient, after forty-eight hours, both eyes were closed, the lips were swollen until the nose was blocked, the ears were about twice the normal size, and the erysipelatoid area had included the scalp, the eyelids, the neck, and the breast. To the horror of the family physician, I painted the entire area at one sitting, painting and carefully neutralizing with alcohol in small sections. The time consumed to do this effectually was nearly two hours. The patient had a temperature of neary 103°, extreme prostration, nausea, and slight delirium. The following day the temperature and pulse were normal, appetite had returned, the pain had entirely disappeared, and, except for the disfigurement, the patient felt quite happy. Within two weeks the superficial layers of the skin had peeled, leaving behind no scars, but a smooth, slightly pinker epithelium than normal. Within one month the complexion was perfect, and the patient expressed herself as being so pleased with the result that she would willingly have undergone the erysipelas and treatment for the sake of the complexion resulting.

If the treatment is properly carried out, no scaring results. The superficial layers of the skin come off as in a mild sunburn. The skin beneath is only slightly tender. One application is usually sufficient to control the inflammation. The after treatment consists in the use of moist dressings of almost any sort. Saline or 1:20,000 bichloride solution has been my choice. I wish to warn against the use of weak solutions of carbolic acid used as wet dressing, both in these and in other cases. The maceration of the skin resulting from the moist dressing allows the absorption of carbolic acid, and sloughing of tissue follows. The use of the 95 per cent. carbolic in its action upon the skin inhibits of itself the absorption into deeper areas.

Etiology of the Pulmonary Affection in Typhoid Fever.—P. Stefanelli has examined the blood of fifteen patients suffering from typhoid fever in whom there existed a localization of the disease in the respiratory organs, to ascertain whether the bacilli found there were pneumococci or bacilli of Eberth. The excreta were also examined. In fourteen of these cases the bacillus of Fraenkel was found in the blood at the time of the pulmonary trouble. The serum reaction for the diplococci was positive in all the cases in which it was not possible to demonstrate the diplococcemia. The Widal reaction remained positive throughout the cases. The excreta were full of diplococci. In six cases the bacillus of Eberth was isolated from the sputum, but this germ was not found in the blood except in one case. The author believes that the typhoid bacillus causes congestion of the lungs and prepares the ground for an easy reception of the pneumococcus, which is favored in its action by the position of the patient on his back, by the poor ventilation of the respiratory tract, and the deficient energy of the cardiac systole.—*Rivista Critica di Clinica Medica.*

Side-Lights on Nature's Opsonic Methods. J. B. Cleland calls attention to certain facts observed by him in Australia. He notes that while experimenting with trypanosome camels in an out-of-the-way part of this State one of the dogs used for inoculation purposes was deeply mauled in the side and round the sheath by another dog, or perhaps dingo. The wounds were very deep and burrowing and the dog was much injured. They soon became foul with extensive sloughing and retention of discharge in the deep parts and, in spite of all attention we could bestow, fatal result was feared. At this stage the animal slept outside the tent at night near a nest of sugar ants, which had annoyed us by their nightly predations on our meat and jams. In the morning it was found that these little creatures had crawled all through the depths of the wounds and had removed the evil-smelling sloughs and pocketed discharge, leaving a clean slightly moist surface through which serum with fresh contents of opsonins could percolate freely. These ants seem rarely to bite and the dog allowed them to continue their operations without any attempt to lick them away, with the result that granulation and healing proceeded apace. During the daytime the flies hovering round the wound also much annoyed the dog, but his attention to them was also rendered unnecessary when a long tailed lizard perched on his side and caught them. It seems to be a practice in some parts of Australia to cure fistula in horses by deliberately "blowing" the sores with flies. The opsonic theory here, again, explains the good results. The maggots eat away the indurated walls, leaving a new surface through which serum rich in opsonins can pass, and thus, as the larvæ die or are washed out, cure follows.—*The Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, February 13, 1909.

THE OPIUM QUESTION.

IT is a matter of common knowledge that a vigorous campaign, or as vigorous a campaign as the lethargic Chinese temperament will permit, is being carried on in China against the opium habit, and a very interesting annotation in the *Lancet* of January 16, from the China correspondent of that journal, throws much light on the progress that is being made. It appears that this progress is distinctly slow, and that, while prominent officials are punished from time to time for indulging in the practice, vast numbers of the common people still smoke. This, according to the *Lancet* correspondent, is chiefly due to the immense size of the empire, its decentralized condition, and the lack of communications, all of which render it extremely difficult to carry out the decrees of the Central Government effectively. Further, a very large number of people "have vested interests in the growth, manufacture, and sale of opium, and it is a large item of national revenue from which numerous officials 'squeeze' sums of varying amount as it passes through their hands."

The statement of a correspondent from Shan-si included in the letter from which we have quoted is so much to the point that it is worth repeating: "Up to the present the edicts and prohibitions have been largely neutralized and the blame lies chiefly with the magistrates. In one city the traffic has been worse than before; the opium shops were supposed to be closed and so no tax was imposed, and in consequence of this a larger number of shops than ever were opened, the magistrate winking at the fact as the profits were higher."

In many Far Eastern countries corruption is rampant and conservatism hidebound, and it is then a matter not calculated to excite surprise to learn that the opium habit is dying hard in China. As the element of farce enters into most human affairs, even the most grave and important, it is not to be wondered at that it is found even here. The account to which reference has been made says: "A quaint touch of Oriental ingenuity to harass the persistent habitués of the drug has been invented by the superintendent of police at Canton. This official has issued 20,000 wooden licenses, ten inches long by eight inches broad and three-fifths of an inch thick. On the front of these boards are characters giving the smoker's name and address and the quantity allowed him per diem, and on the back are the opium regulations. The licensees are not allowed to cover their boards when going to buy opium but must wear them conspicuously so that all may see them. Next year these wooden licences are to be two feet long by one and a half feet broad and three-fifths of an inch thick. If the government were to go doubling the size of them progressively in each successive year it would become ridiculous ere long. Yet it is said that this is positively the intention of the authorities."

Although the consumption of opium to excess by members of the white races is harmful in a high degree to body and mind, the effect of the drug upon the Far Eastern races is a point concerning which no such dogmatic statement can be made. Of course there are to be found in Asia among the native population thousands of men and women who are slaves to the habit and who are thereby demoralized in mind and ruined in constitution. On the other hand there are immense numbers of people who while accustomed to take opium daily consume the drug in moderate quantities and exhibit no evil effects from the practice. Indeed Mr. Rudyard Kipling some years ago stated that in his belief the moderate consumption of opium did good rather than harm to the native population of India. In fact, the consumption of opium by the Asian people may be compared not inaptly to the consumption of alcohol by Europeans. Both have through generations of practice acquired a certain immunity to the drugs. This, however, does not prove that alcohol and opium are not harmful, but that narcotics of any description exert an especially malign influence upon virgin soil. Thus the consumption of opium by white people is invariably attended with the most disastrous consequences and every available step should be taken to discountenance and put down the habit. It is to be hoped that the deliberations of the forthcoming International Opium Commission at Shanghai may be potent in this direction, and that much useful information on the subject may be tendered, and suggestions with regard to stopping the opium traffic in New York and elsewhere in America be brought forward by the American delegates to this convention.

FLAGELLATION OF LYMPHOCYTES UNDER THE INFLUENCE OF CANCER SERUM.

WE referred last week to a curious phenomenon observed by Ross and Macalister in relation to the blood serum of cancer patients. These investigators announced that there was a something in the blood of sufferers from carcinoma which acted as a peculiar excitant to the leucocytes of healthy persons. In a second paper, in the *British Medical Journal* of January 23, they discuss the nature of this excitation, the process being apparently the same, whether an artificial excitant, such as atropine sulphate, or the blood serum from a cancerous patient is used.

The phenomenon, observed only in the lymphocytes, large and small, is one of flagellation and the extension of minute granules of chromatin.

Most authorities state that the lymphocytes contain no granules or at most only very few. This appears to be true in fixed films where the cells are dead, but when living mononuclears are examined, the writers assert, there will be seen in the cytoplasm a few deeply stained granules around the nucleus. These granules are somewhat smaller than those of the eosinophiles, but larger than those of the polymorphonuclears. The process of flagellation in these cells is described as follows: When the specimen has been examined with methylene-blue and one is looking over the field for large and small lymphocytes having bright discrete granules, suddenly one meets with a cell, which may or may not have been extruding pseudopodia, probably not, and which appears to have a granule dancing about, as though by Brownian movement, just outside the cell wall. This granule is attached to the cell by a thin hair-like filament. The flagellum is seen to be gradually further extruded until it may become longer than the width of the cell. There may be several of these flagella, each with a brightly stained granule at its extremity and sometimes with others at intervals along the length of the filament. They are readily distinguished from pseudopodia and from threads of fibrin. After a while they usually break away and progress, nodule first, through the plasma.

E. H. Ross, on observing one of these flagellated lymphocytes, remarked on its resemblance to the malarial gametocyte, and suggested that the flagella might be spermatozoa. There are, no doubt, certain cytological difficulties in the way of this suggestion, but the authors hold that these difficulties are not insuperable and do not render the suggestion untenable. They draw attention to the possibility of the brightly staining granules in the lymphocytes being chromatin and of the nodule at the end of the flagellum being one of these granules. Chromatin bodies in the cytoplasm have been described by Hermann as derived from the nucleus, and it has been suggested that they form the extruded male element. If this is so, then it is not improbable that these flagella are, as E. H. Ross suggested, spermatozoa; and since they are produced by some excitant in the plasma of cancer patients, Ross and Macalister conclude that they may play an important part in the causation of the disease, or at least in the pathogenesis of the carcinoma. But what cells may be fertilized by these spermatozoa, if such these granules are, the authors are as yet unable to say and wisely refrain from speculating.

Everyone is, however, at liberty to speculate for himself regarding the nature of these flagella and the possible rôle they may play in the pathogenesis of carcinoma, and such speculation opens up great vistas of possible advances in our knowledge of cancer. This observation may, of course, like so many other supposed discoveries—especially, perhaps, in the line of cancer investigation—lead to nothing, but the authors of the paper are careful observers, and there is no doubt that others will take up the matter and confirm or disprove their findings.

DISEASES TRANSMITTED BY ANIMALS TO MEN.

The transmission of disease is one of the most important and interesting questions with which medical science has to concern itself. To say that our views in this direction have undergone a considerable change within the past few years would be to state the case mildly. It would be little exaggeration to say that a revolution of our ideas as to the transmission of disease has taken place. It is now known by everyone that insects convey numerous complaints to man, perhaps almost all the tropical maladies, including malaria, yellow fever, and sleeping sickness. Plague is believed to be transmitted to man chiefly by means of rats or their fleas. Tuberculosis, despite the dogmatic statements of Koch, is in certain circumstances conveyed to the human race, mainly to children, by the agency of cattle. More than this, the opinion has been rapidly gaining ground of late years that domestic animals are responsible to some extent for spreading several infectious diseases. The cat has been under suspicion for many years, and it has been alleged with foundation for the statement that the parrot has passed on disease to some of those who have come into close contact with him.

Cohen has said, in his "System of Physiological Therapeutics," that the lower animals, such as cats, dogs, horses, cattle, and chickens, occasionally suffer from a pseudomembranous affection of the upper respiratory passages simulating diphtheria, and from this infection has been claimed. He, however, states that it is rare that true diphtheria bacilli are found in these animals, although they have been found susceptible to the disease experimentally produced. Osler is of much the same opinion, and so are, perhaps, the majority of veterinary experts. The point really that requires solution is this: Does the cat contract diphtheria, a disease to which cats are subject, from a person suffering from the complaint or does the animal merely act mechanically as a carrying agent?

Recently, Dr. Caroline A. Osborne has endeavored to answer these questions in a small book entitled "The Cat, a Neglected Factor in Sanitary Science." From this we learn that, as mentioned before, Osler and Cohen, together with the larger number of veterinary authorities, hold that the cat does not contract diphtheria from the human subject, nor do they think that it transmits the disease to man, at least they argue that the proofs to this effect are very slight. On the other hand there are many authorities who contend that cats suffer from true diphtheria and also convey it to men. Klein is said to believe that diphtheria is a natural disease of the cat and it has also been asserted upon responsible authority that during widespread epidemics of diphtheria, a similar affection of the throat may be found in cats, pigeons, fowls, etc. Dr. Louis W. Sambon, the distinguished authority on tropical diseases, read a paper before the British Royal Society of Medicine, published in the *Lancet* April 18, 1908, in which he supported, by statistics, the theory that diphtheria is transmissible between man and the lower animals.

Even if diphtheria is not contracted by cats, it seems to have been proven in a sufficiently conclusive manner that they will carry the infection and are therefore a source of considerable danger. Cats are known to suffer from other diseases which are transmissible to man, such as scabies and ringworm, and a cat with mange is a fertile agency of infection to the domestic animals of a neighborhood.

Etiological Therapy of Syphilis.

There is no doubt that the most promising method of treatment in disease is that which depends upon the use of remedies that are directly antagonistic to its excitants, whether these remedies are drugs or sera or vaccines. Specifics among drugs, however, have been discovered in but few instances only, and the search for them consists, of course, in the very empirical method of trying every possible remedy that may be thought to prove effective. Specific treatment by means of sera or other artificial or natural products of the animal organism, on the other hand, is usually undertaken on more logical grounds, the production of such substances being founded on animal experimentation, the circumstances of which are to a certain degree under the control of the experimenter. In the treatment of syphilis mercury has always been regarded as a specific; yet the mere fact that this drug must be used for a long time and its administration must be repeated on several occasions before final cure is obtained shows that the specific action of the drug, although possessed by it more than by any other remedy known to us, is still far from being as powerful as that of quinine in malaria, for example. During recent years, therefore, many experimenters have tried to obtain better results with the use of products from animals which had received injections of syphilitic material or from human beings suffering from the disease. In the *Deutsche medizinische Wochenschrift* for January 7, 1908, Dr. Spitzer reports the success he has had with an original application of such treatment, consisting in the subcutaneous injections of substances prepared from the primary lesions of syphilis. In the first series of patients treated in this manner it was noted that the existing lesions of the disease underwent a very rapid involution; in a later series, in which treatment was begun much earlier, ten patients escaped all the secondary manifestations of a luetic infection, though the period of observation extended over two years. The diagnosis was in several cases corroborated by the demonstration of the *Treponema pallidum* in the primary lesions, while the existence of cure was shown, in addition to the clinical evidence of the failure of secondary manifestations to make their appearance, by the negative results of the Wassermann reaction for syphilis. In one case treated in this manner a second infection, with the appearance of a typical sclerosis and the presence of the organisms of syphilis, occurred two and one-half years after the first infection. As it is generally agreed that syphilitic patients cannot be reinfected during the active stage of the disease, the evidence of cure was greatly strengthened by this occurrence. Spitzer concludes that the infected tissues, when injected according to his technique, exercise a curative action upon the disease. That a more effective manner of using such tissues may be devised is, of course, probable; the present task of other experimenters, however, is to follow the suggestion of Spitzer, in order that the results obtained by him may be sufficiently corroborated to be accepted and used for the development of better therapeutic measures of the same general character.

The Prevention of Blindness.

A movement which is full of promise for happiness to many hundreds and thousands of children yet unborn was started not long since and has already grown to very large proportions. This is the effort being made by ophthalmologists, obstetricians, and sanitarians to bring home in a forcible manner to both physicians and the laity the absolute necessity of guarding the eyes of the newborn against the sight-destroying specific ophthalmia. One of the most recent agencies in this propaganda is the Special Committee on the Prevention of Blindness of the New York Association for the Blind, the establishment of which was rendered possible in the spring of 1908 through the generosity of a lady in this city. The object of this Committee is to ascertain the direct causes of preventable blindness and to take such measures as may lead to the elimination of these causes. The prevention of ophthalmia neonatorum is the principal aim of the Committee, and they seek full cooperation with the medical profession, the State and City Boards of Health, the State and County Societies, and all organizations or persons interested in the subject. This committee has recently issued the second of its pamphlets for popular instruction, appealing strongly to the reader through pictures of sightless children who need not have been blind. This will doubtless be a strong ally of the purely medical organizations already active in the campaign of education regarding preventable blindness.

News of the Week.

The Anesthetic Clause in the Antivivisection Bill.—In a recent reference to the Davis antivivisection bill now before the New York Legislature, we were in error in assuming that anesthetics must be used in all cases. The bill provides that anesthetics need not be used in the following cases: "(*a*) In tests of food, drugs, or serums; (*b*) in so-called inoculation experiments; (*c*) in investigations regarding the communicability of human or animal diseases; (*d*) in experiments involving the relation of the parts of the body to consciousness; (*e*) during the process of recovery from any experiment; provided, however, that any cutting operation must be done while the animal is in a condition of insensibility produced by anesthetics."

Red Cross Stamps.—The committee of the New York County Branch of the Red Cross which had in charge the distribution of the stamps for Christmas packages, each stamp representing a contribution of one cent to the fund for tuberculosis work, has reported that the total receipts from the sale of the stamps in Manhattan and the Bronx were $15,488.01, the net receipts being $11,270.38. Of this amount, $5,000 has already been pledged for the maintenance of the Red Cross Day Camp for Tuberculous Patients on the roof of the Van-

derbilt Clinic, and $1,000 has been given towards defraying the expenses of the recent tuberculosis exhibition at the American Museum of Natural History. The remainder will be used for further day camps. The committee has decided to make the Christmas sale of the Red Cross stamps a permanent feature of the holiday season, and to confine its use as a means of collecting funds to the anti-tuberculosis work.

No Basement Bakeries.—The Chicago Health Department has begun active steps to enforce the ordinance governing bakeshops, and has served notice that bakeries must be removed from basements and from ill-ventilated rooms. Many of the largest hotels and restaurants in the city, more especially in the downtown districts, have their bakeries situated in the basement or even the subbasement, where they do not receive sufficient fresh air or sunlight.

Opium Congress.—The International Congress to discuss the control of traffic in opium opened at Shanghai, China, on February 1, Bishop Brent of the Philippines, senior American delegate to the conference, being elected chairman.

Marriage Among Consumptives.—A bill has recently been introduced into the Pennsylvania State Legislature designed to regulate the issuance of marriage licenses. The bill provides that a marriage license shall not be issued until each of the applicants therefor shall present to the clerk a certificate from an authorized practitioner setting forth that, to the best of his knowledge and belief, the person applying for the license is not afflicted with pulmonary tuberculosis, epilepsy, insanity, imbecility, idiocy, or other hereditary disease.

Dr. William George MacCallum has been elected to succeed Professor T. Mitchell Prudden in the chair of Pathology at the College of Physicians and Surgeons, Columbia University, New York. Dr. Prudden, as already announced, will retire at the close of the present academic year. Dr. MacCallum is a Canadian, and a graduate of the University of Toronto in the class of 1894, and of the Johns Hopkins Medical School in the class of 1897. At present he occupies the position of Associate Professor of Pathology at the Johns Hopkins Medical School.

Epidemics in Mexico.—The epidemic of scarlet fever in Mexico City is reported as being under control. At Zacatecas, smallpox has been epidemic, and within three days 1,200 children were vaccinated in the attempt to check the disease. Typhoid fever has been extremely prevalent in Oaxaca and there have been many deaths. At Guaymas, bonds to the amount of $60,000 have been issued, the proceeds to be used for sewers and waterworks to guard against yellow fever. Construction work will begin at once.

Dr. M. J. Seifert has been appointed attending surgeon to St. Mary's of Nazareth Hospital, Chicago.

Health of the Canal Zone.—The report of the department of sanitation for the month of December, 1908, shows that while the sick rate for the month showed a slight improvement over that for November, being 25.95 per thousand, as compared to 27.16 per thousand, the death rate shows a considerable increase. This increase, however, was largely due to the fact that the number of deaths from violence during December was the largest in the history of the work on the Isthmus, being 48.6 per cent. of the total number of deaths. Considering only the deaths from disease, the rate shows a considerable improvement, being 12.81 per thousand for December, 1908, and 14.69 for December, 1907, the total number of deaths being 50 and 44, respectively. The total rate for the Canal Zone, including employees and non-employees, was 20.75, while for Panama and Colon the rate was 33.28. No cases of yellow fever, smallpox, or plague have occurred.

Prof. Irving Fisher of Yale University addressed the Association of Life Insurance Presidents and invited guests at a meeting in New York, on Friday, February 5, on the promotion of hygienic conditions and public health.

Trustees of Bellevue.—Dr. John Winters Brannan, President of the Board of Trustees of Bellevue and Allied Hospitals, whose term recently expired, has been reappointed by the Mayor. Mr. James A. Farley has also been appointed to succeed John J. Barry recently made Commissioner of Correction.

Low Death Rate.—Springfield, Mass., reports for 1908 the lowest death rate in seventeen years. The total number of deaths during the year was 1,224, making a rate of 15.03. An increase in the number of cases of diphtheria during the year was reported, but cases of scarlet fever and typhoid fever show a decided decrease. The report of the Board of Health strongly urges more sanitary methods in the cleaning of school rooms, and recommends medical and dental inspection of school children.

Vital Statistics in New Jersey.—The report of the New Jersey State Registrar of Vital Statistics for the month of January shows 3,164 deaths, which is 117 less than for the corresponding month of last year. Of the deaths, 602 were of children under one year of age, 267 were of children between the ages of one and five, and 982 were of persons sixty years of age and over. There was a large increase in the number of deaths from pneumonia and from cancer. The suicides numbered 44, the largest number for any month in the past half year.

New York Milk Committee Lectures.—A series of lectures on infant feeding and hygiene has been arranged by the Association of Physicians of the New York City Milk Depots, to be given in the Assembly Hall of the United Charities Building, at 105 East Twenty-second street, during February, March, and April. The lectures are intended for all doctors, nurses, social workers, and other individuals interested in the problem of the mother and her child. The program is as follows: February 19, General Principles of Infant Feeding, by Godfrey R. Pisek, M.D.; March 3, Value of Fats in Infant Feeding, by John Howland, M.D.; March 13, Infant Feeding: Its Relation to Infant Mortality, by Joseph E. Winters, M.D.; March 26, Value of Carbohydrates in Infant Feeding, by Henry Dwight Chapin, M.D.; April 14, Milk Sanitation, by Rowland G. Freeman, M.D.; April 23, Hygiene of Infancy, by William P. Northrup, M.D.; April 30, Dietary of Children After the First Year, by I. E. LaFetra, M.D. The lectures will be given at three o'clock in the afternoon.

Vital Statistics in New York.—The State Health Department, in a bulletin issued on February 5, reported that there were 133,441 deaths in

New York State in 1908, or 8,449 less than in 1907. The total number of births recorded was 203,159, against 195,735 in 1907. New York City, with nearly half the total population, reported 73,075 deaths. Troy showed the highest death rate and the lowest birth rate. The total number of deaths from tuberculosis was 16,521, about 12 per cent. of the total mortality. Typhoid fever showed a total of 1,368 deaths, or 305 less than in 1907, and pneumonia 8,602 deaths, a decrease of 2,412 from the total for 1907.

Fellowship in Pathology.—Announcement is made by the Committee on the George Blumenthal, Jr., Fellowship in Pathology, Mount Sinai Hospital, New York, that the Committee will meet in March for the appointment of a Fellow for the ensuing year. The Fellowship carries an allowance of $500 per annum and all graduates in medicine are eligible. The object of this Fellowship is to further the scientific work of the hospital and to aid graduates in medicine who are anxious to obtain thorough laboratory training. The work done under the Fellowship may be carried on either in Mount Sinai Hospital or elsewhere, according to agreement with the Committee in charge. Applications for this appointment will be received on or before March 15, 1909, by Dr. F. S. Mandlebaum, Pathologist, Mount Sinai Hospital.

Gifts to Charities.—By the terms of the will of the late Max Freund of New York, Mt. Sinai Hospital receives $1,000, and the Montefiore Home for Chronic Invalids and Lebanon Hospital, each $500. The will of the late Mrs. H. W. Miller of Providence, R. I., provides for the endowment of two beds in the Rhode Island Hospital, to be known as the "Horace George Miller Free Bed," and the "Helen Woods Miller Free Bed." The Rhode Island Medical Society receives a fund of $5,000 the income of which is to be applied to caring for, binding, and repairing of the library given to the society by the late Dr. Miller, the husband of the testator, or for the purchase of new books.

The Springfield (Mass.) Hospital has received a gift of $10,000 in memory of Mrs. Louisa J. G. Pease, to be used for an additional operating room.

The East Side Physicians' Association.—A clinical meeting of this Association will be held at the Café Boulevard, New York, on Friday, February 19, at 8.30 P.M., and an attractive program has been arranged. The annual dinner of the Association will be given at the Hotel Majestic on February 24.

The Elkhorn Valley (Neb.) Medical Association, at its annual meeting at Norfolk, on January 19, elected the following officers: *President,* Dr. J. M. Aiken, Omaha; *Vice-Presidents,* Dr. A. B. Tasjean, Norfolk, and Dr. A. C. Johnson, Creighton; *Secretary,* Dr. W. R. Peters, Stanton; *Treasurer,* Dr. W. Pilger, Norfolk.

San Francisco County Medical Society.—At a recent meeting of the directors of this society, Dr. August J. Lartigau, formerly of New York, was elected president. Dr. Lartigau has served as librarian of the society for some time.

The Red River Valley (Mich.) Medical Association held its annual meeting on January 27. The following officers were elected for the ensuing year: *President,* Dr. H. Holte, Crookston; *Vice-President,* Dr. Bratrud, Warren; *Secretary and Treasurer,* Dr. H. E. Nelson, Crookston; *Board of Censors,* Dr. H. C. Stuhr, Argyle; Dr. I. Lemiex, Red Lake Falls, and Dr. C. H. Denniston, Crookston; *Delegate to State Meeting,* Dr. C. E. Dampier, Crookston.

The State Charities Aid Association held its annual meeting at Albany on February 2. The Hon. Joseph H. Choate presided. At the evening meeting Governor Hughes spoke on "Cooperation of Private and Public Agencies in Preventive Philanthropy." Dr. Albert W. Ferris, president of the State Commission in Lunacy, also spoke on "Avoidable Causes of Insanity," and Dr. Livingston Farrand emphasized the need of hospital accommodations for advanced and hopeless cases of tuberculosis, as well as for the incipient and curable cases.

Indianapolis Medical Society.—At the annual meeting held January 5, the following officers were elected: *President,* Dr. Theodore Potter; *Vice-President,* Dr. Walter N. Sharp; *Secretary-Treasurer,* Dr. Roscoe H. Ritter; *Delegates to the State Medical Association,* Drs. Allison Maxwell, Albert C. Kimberlin, and Edmund D. Clark: *Alternates,* Drs. Thomas B. Eastman, William T. S. Dodds, and Charles R. Sowder.

Central Texas District Medical Association.—The annual meeting of this association was held in Waco January 12 and 13, 1909. The opening session was called to order by the Chairman of the Arrangement Committee, Dr. M. B. Saunders of Waco. In the Section of General Medicine, the Chairman being absent, Dr. O. I. Halbert, Secretary, presided, and the following papers were discussed: "Report of a Case of Chronic Interstitial Nephritis with Death from Uremia," by Dr. S. B. Kirkpatrick, Waco; "The One Universally Applicable Diagnostic Test for Tuberculosis and the Three Fundamental Factors in its Treatment," by Dr. Boyd Carnick, San Angelo; "Some Remarks on Malarial Fever," by Dr. J. A. Tate, Ennis; "Electricity in General Medicine," by Dr. J. M. Martin, Dallas; "Chorea," by Dr. J. F. Ford, Decatur; "Malarial Hematuria and Hemoglobinuria," by Dr. A. S. Epperson, Cameron; "Treatment of Amebic Infection," by Dr. M. B. Saunders, Waco. In the Section of Gynecology and Obstetrics, Dr. W. E. Sturgis, Stephenville, chairman, the following papers were read: "Chairman's Address," by Dr. W. E. Sturgis, Stephenville; "Report of an Interesting Gynecological Case," by Dr. J. M. McCutchan, Waco; "Puerperal Fever," by Dr. H. E. Connelly, Eddy; "The Relation Between Some Perineal Lacerations and the Neurasthenic State," by Dr. H. M. Johns, Waco. In the Section of Surgery, Dr. William Yater, chairman, the following papers were read: "Aneurysm of the Ascending Aorta," by Dr. G. B. Fosque, Waco; "Gunshot Wound of the Abdomen," by Dr. J. W. Hale, Waco; "Surgical Aspect of Kidney Lesions, Including Diagnosis," by Dr. J. L. McGlasson, Waco; "What I Have Seen in Baltimore," by Dr. H. K. Ainsworth, Waco. Following each of these papers was a general discussion of the subject, and it was the opinion of those present that the personnel of the program, the character of the papers, and the discussions have never been better in the history of the Central Texas District Medical Association. On Tuesday night, at 8:30, the retiring president, Dr. W. A. Wood of Hubbard City, delivered his annual address, in which he gave an interesting history of the Central Texas District Medical Association and paid a glowing tribute of respect to the living and to the dead ex-

presidents. During the latter part of the first day's session the association enjoyed a visit from the majority of the Board of Counselors of the State Medical Association, and at this time there was a general discussion upon the subject of division of fees. Several members of the Board of Counselors took part in this general discussion. This question is being agitated by men in certain sections of the State, but it was the consensus of opinion of those present, including the Board of Counselors, that these methods should under no circumstances be encouraged or countenanced by the medical profession of Texas. The election of officers resulted in the choice of the following: *President*, Dr. M. P. McElhannon, Belton; *Secretary*, Dr. William Yater, Cleburne. Marlin, Texas, was selected as the place of meeting and the president announced the following appointments: *For the Section of Practice*, Dr. W. H. Allen, Marlin, chairman; Dr. J. W. Gibney, West, secretary. *Section Ear, Eye, Nose, and Throat*, Dr. W. R. Washburn, Cleburne, chairman; Dr. B. L. Scott, Waco, secretary. *Section of Gynecology and Obstetrics*, Dr. R. R. White, Temple, chairman; Dr. A. O. Cragwall, Stephenville, secretary. *Section of Surgery*, Dr. R. B. Sellers, Comanche, chairman; Dr. R. J. Alexander, Waco, secretary.

Obituary Notes.—Dr. ALEXANDER WILLIAMSON of Asbury Park, N. J., died at his home on February 2 of heart disease, aged 61 years. He was graduated from the medical department of the University of Pennsylvania in 1878.

Dr. JOSEPH BERNARD MAUCH of New York died suddenly at his home on February 2. Dr. Mauch was born in Germany in 1849. He was a member and the last survivor of the North Pole expedition of 1871-1873 on the steamer *Polaris*, serving as clerk to the commander. He was graduated from the College of Physicians and Surgeons, New York, in 1886.

Dr. JOHN JAMES MITCHELL of Newburgh, N. Y., died suddenly on February 1, aged 75 years. Dr. Mitchell was graduated from the University of New York in 1857. He was a member of the American Institute of Homeopathy and of the State Homeopathic Society. After serving as City Physician in Brooklyn for a short time, Dr. Mitchell in 1859 removed to New York, where for several years he occupied the chair of chemistry in the New York Homeopathic Medical College. In 1869 he removed to Newburgh. In 1883 he was elected president of the State Homeopathic Medical Society.

Dr. GORDON W. RUSSELL of Hartford, Conn., a graduate of the Yale Medical School in the class of 1837, died at his home on February 3.

Dr. EDWIN C. DENNIN died in the Long Island College Hospital on February 1, aged 40 years. He was a graduate of the New York School of Pharmacy and of the Long Island College Hospital.

Dr. CHARLES E. HOYE of Seattle, Wash., died on January 24 of disease of the kidney, aged 43 years. Dr. Hoye was graduated from the medical department of the University of New York in 1889.

Dr. DANIEL JAMES HANLON of Hyde Park, Mass., died suddenly on January 24, while making a professional call. Dr. Hanlon was born in 1867, and was graduated from the Boston University Medical School in 1891. He was a member of the American Medical Association.

Dr. DAVID L. DOUGLASS of Colfax, Ill., died of paralysis at the home of his brother in Morristown, N. J., on February 5. He was a graduate of the University of Chicago.

Correspondence.

WELLS AND DARWIN AND THE DOCTRINE OF EVOLUTION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—William Charles Wells, one of the world's great men, was born in Charleston, S. C., May 25, 1757. His parents came to America from Dumfries, Scotland, in 1753. Wells was probably the leading intellect of his century, yet his name is omitted in some of the chief encyclopedias, and in some of the biographical reference books he is mentioned only in connection with his scientific essay on dew. After winning in science, handicapped by poverty and disease, Wells died in London September 18, 1817. His genius has brought to England much of her renown in science, and his fame is for the future.

About a century ago Wells enunciated the doctrine of evolution which has revolutionized thought. He applied his discovery in evolution to the solution of "that mystery of mysteries," and thus put into the hands of the scientific a model in practical working order for thinkers to follow in solving problems of life.

Wells' remarkable essay was read before the Royal Society in 1813. Although he was eminent in science, his brief paper is omitted in the printed Transactions of the Royal Society, but this omission may be attributed to the intellectual originality of the essay. New intellectual science, even though presented in simple language, is usually not understood until it receives the attention and study of great interpreters.

The Origin of Species, published by Charles Darwin in 1859, seems to have been a development of the line of thought of Dr. Erasmus Darwin, his grandfather, who pondered over this problem. Wells criticized some of the elder Darwin's theories, and in his memoir writes that he was attacked in print by him. Wells' solution of the problem of the origin of species was given to the world subsequent over the controversy with Dr. Darwin, and after the latter had come to an erroneous conclusion regarding the origin of species.

Darwin idolized his grandfather, but while he gave studious attention to his works and frequently with just pride spoke of his genius, his attention may never have been called to the controversy or to Wells' extensively read essays, published in 1818. Wells and Darwin were distinctly honored members of the Royal Society. Wells received its Rumford medal. Singularly, Darwin seems to have read everything written on this deep theme with the exception of Wells' essay.

Darwin's modesty is proverbial, and had he looked more carefully into the literature at home, it is probable that Wells' discovery would have been set forth in the first edition of "The Origin of Species," a work slowly, deliberately, and carefully written. In the later editions, Darwin acknowledges his indebtedness to Mr. Rowley, of the United States, for calling his attention to the essay of Wells, which Darwin at that time seemingly had not read. The "Historical Sketch" then appears and attention is directed to many writers; some of these have ingenious theories, others have claims of independence in discovery and of precedence in promulgation; further, scientists of originality and ability are quoted. In reviewing the work of more than a score of writers, "the first recognition" and "the mere enunciation of the principle of natural selection" are referred to, but the scope and magnitude of Wells' discovery, as well as his scientific presentation of creative thought, are overlooked. Darwin writes: "In this paper he" (Wells) "distinctly recognizes the principle of natural selection, and this is the first recognition which has been indicated; but he applies it only to the races of man, and to certain characters alone." After remarking that negroes and mulattoes enjoy an immunity from certain tropical diseases, he observes, firstly, that all animals tend to vary in some degree, and, secondly, that agriculturists improve their domesticated animals by selection; and then, he adds, but what is done in this latter case "by art, seems to be done with equal efficacy, though more slowly, by nature, in the formation of varieties of mankind, fitted for the country which they inhabit."

The casual reader can see from the above excerpt, or from the text printed below, that Wells' doctrine applies to all animals.

Alfred Russell Wallace, whose independent discovery of the principle of natural selection is set forth by Darwin, claims the independent discovery, not only for himself, but for Darwin also. Before the Linnean Society, in celebration of the fiftieth anniversary of the reading of the views of Darwin and Wallace, the latter is reported to have said

that "during the first half of the nineteenth century many biological thinkers and workers had been pondering over the problem and had even suggested ingenious, but inadequate solutions." Why did so many of the great intellects fail, he asked, while Darwin and he (Wallace) hit upon the solution? Wallace in endeavoring to explain why the same solution of the problem of the origin of species had occurred to both of them, pointed out that a closely similar course of events had led up to the same result in each case.

Wells' essay is a paragon of scientific observation and intellectuality, and as a model for evolutional thought has never been surpassed. The original essay has never been in print. The edited essay has been in type but once, in 1818. It is now rare. The MEDICAL RECORD may do science a great benefit by reproducing below about one-half of Wells' essay.

N. B. JENKINS, M.D.
175 FIFTH AVENUE, NEW YORK.

SOME OBSERVATIONS ON THE CAUSES OF THE DIFFERENCE IN COLOR AND FORM BETWEEN THE WHITE AND NEGRO RACES OF MEN.—BY WILLIAM CHARLES WELLS, M.D., F.R.S., L. & E.

"On considering the difference of color between Europeans and Africans, a view has occurred to me of this subject, which has not been given by any author, whose works have fallen into my hands. I shall, therefore, venture to mention it here, though at the hazard of its being thought rather fanciful than just.

"There is no circumstance, perhaps, in which these two races differ so much as in their capacity to bear, with impunity, the action of the causes of many diseases. The fatality to Europeans of the climate of the middle parts of Africa, which are, however, inhabited by negroes without injury to their health, is well known. Let it then be supposed that any number of Europeans were to be sent to that country, and that they were to subsist themselves by their bodily labor; it seems certain, that the whole colony would soon become extinct. On the other hand, the greater liability of negroes in Europe to be attacked with fatal diseases is equally well established. If, therefore, a colony of the former race were brought to Europe, and forced to labor in the open air for their subsistence, many of them would quickly die, and the remainder, from their inability to make great bodily exertions in cold weather, and their being frequently diseased, would be prevented from working an equal number of days in the year with the whites. The consequence would be, that without taking farther into account the unfriendliness of the climate to them, their gains would be inadequate to the maintenance of themselves and their families. They would thence become feeble, and be rendered still more incapable of supporting life by their labor. In the meantime, their children would die from want, or diseases induced by deficient or improper nourishment, and in this way a colony of the negro race in a cold country would quickly cease to exist.

"This difference in the capacity of the two races to resist the operation of the causes of many diseases, I assume as a fact, though I am utterly unable to explain it. I do not, however, suppose that their different susceptibility of diseases depends, properly, on their difference of color. On the contrary, I think it probable that this is only a sign of some difference in them which, though strongly manifested by its effects in life, is yet too subtle to be discovered by an anatomist after death; in like manner as a human body, which is incapable of receiving the smallpox differs in no observable thing from another, which is still liable to be affected with that disease.

"Regarding then as certain that the negro race is better fitted to resist the attacks of the diseases of hot climates than the white, it is reasonable to infer that those who only approach the black race will be likewise better fitted to do so than others who are entirely white. This is, in fact, found to be true with regard to the mixture of the two races: since mulattoes are much more healthy in hot climates than whites. But among men, as well as among other animals, varieties of a greater or less magnitude are constantly occurring. In a civilized country which has been long peopled, those varieties for the most part quickly disappear, from the intermarriages of different families. Thus, if a very tall man be produced, he very commonly marries a woman much less than himself, and their progeny scarcely differs in size from their countrymen. In districts, however, of a very small extent, and having little intercourse with other countries, an accidental difference in the appearance of the inhabitants will often descend to their late posterity. The clan of the Macras, for instance, possess both sides of Loch-Duich, in Scotland; but those who inhabit one side of the loch are called the black Macras, and the others the white, from a difference which has always been observed in their complexions. Again, those who attend to the improvement of domestic animals, when they find individuals possessing, in a greater degree than common, the qualities they desire, couple a male and a female of these together, then take the best of their offspring as a new stock, and in this way proceed till they approach as near the point in view as the nature of things will permit. But what is here done by art seems to be done with equal efficacy, though more slowly, by nature in the formation of varieties of mankind fitted for the country which they inhabit. Of the accidental varieties of man which would occur among the first few and scattered inhabitants of the middle regions of Africa, some one would be better fitted than the others to bear the diseases of the country. The race would consequently multiply, while the others would decrease, not only from their inability to sustain the attacks of disease, but from their incapacity of contending with their more vigorous neighbors. The color of this vigorous race, I take for granted, from what has been already said, would be dark. But the same disposition to form varieties still existing, a darker and a darker race would in the course of time occur, and as the darkest would be the best fitted for the climate, this would at length become the most prevalent, if not the only, race in the particular country in which it had originated.

"In like manner, that part of the original stock of the human race which proceeded to the colder regions of the earth would in process of time become white, if they were not originally so, from persons of this color being better fitted to resist the diseases of such climates, than others of a dark skin.

"The cause which I have stated as likely to have influence on the color of the human race would necessarily operate chiefly during its infancy, when a few wandering savages from ignorance and improvidence must have found it difficult to subsist throughout the various seasons of the year, even in countries the most favorable to their health. But, when men have acquired the knowledge of agriculture and other arts, and in consequence adopt a more refined mode of life, it has been found that an adherence to their ancient customs and practices will preserve them long as a distinct race from the original inhabitants of the country to which they had emigrated. Examples of this kind are frequent in the islands in the eastern seas in the torrid zone, where the inhabitants of the seacoast, evidently strangers, are in some degree polished, and of a brown color, while the ancient natives, who live in the interior parts, are savage and black. Similar facts occur in respect to other species of animals. It seems certain, for instance, that fine wooled sheep, like the Spanish, never both arose and sustained their breed in the northern parts of Europe; yet, by care this feeble race, after being formed in Spain, has been propagated and preserved in very cold countries. Thus the late Mr. Dryander, the learned librarian of the Royal Society, informed me that the breed of fine wooled Spanish sheep had been kept perfect in Sweden during a very long term of years—I think he said a century. If, then, my memory be accurate upon this point, we have here an example of a variety of animals much more liable to be affected by external circumstances than the human race, being preserved without change in a country very different from their own, by assimilating their new state as much as possible to their old during at least fifty generations, that is, during a period equivalent to 1,500 years in the history of man.

"Hitherto, while speaking of the external appearance of negroes, I have taken notice only of their color. I shall now say a few words upon their woolly hair, and, according to our notions of beauty, the deformity of their features.

"There are several facts which seem to show that these circumstances are somehow connected with their low state of civilization.

"First, the black inhabitants of the Indian Peninsula within the Ganges who, compared with the African negroes, may be regarded as a polished people, have hair and features much less dissimilar to the European.

"Secondly, woolly heads and deformed features appear again as we proceed further to the east among the savage inhabitants of New Guinea and the adjacent islands at the distance nearly of half of the circumference of our globe from Africa, and consequently without the smallest probability of any communication having ever existed between the two countries.

"Lastly, it appears probable from the reliques of ancient

art that the early inhabitants of Egypt were of the negro race. If, then, the negroes of Africa were ever to be civilized, their woolly hair and deformed features would perhaps, in a long series of years, like those of the Egyptians, be changed. On the other hand, their present external appearance may possibly be regarded not only as a sign, but as a cause of their degraded condition, by preventing, in some unknown way, the proper development of their mental faculties; for the African negroes have in all ages been slaves; and the negroes in the eastern seas are in no instance, I believe, masters of their handsomer neighbors, but are in many places in entire subjection to them, though the latter be frequently less numerous.

"It will no doubt be objected to what I have advanced, respecting the difference of color between Europeans and Africans, that the Indian inhabitants of the greater part of the immense continent of America have skins nearly of one hue. Plausible reasons may, I think, be given for this fact, consistently with what has been said upon the color of the two former races; but I forbear trespassing any longer upon the time of the reader in discussing a subject which admits only of conjectural reasoning."

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RESEARCH ENDOWED AT THE LONDON HOSPITAL COLLEGE—HOSPITAL MANAGEMENT, A STATISTICIAN'S VIEW—SEASIDE VS. INLAND RESORTS—OBITUARY.

London, January 22, 1909.

The Medical School of the London Hospital is to be congratulated on the receipt of a small fortune. A sum of £20,000 has been handed by a beneficent anonymous donor to trustees to invest and pay the income to three administrations chosen by the donor, who are to spend it in the advancement of medical research within the walls of the London Hospital or College. The selected administrators are the chairman and two members of the medical staff of the hospital. The benefits will not be confined to students of the hospital, but will be open to qualified men from any part of the empire. The donor wishes to remain anonymous in the hope that the fund thus started may be added to by others and in time become of such magnitude as to serve future generations in the fight against disease.

It is not often that the Royal Statistical Society deals with questions of special interest to medical men, but a paper read on Tuesday demands attention. The author is Mr. P. E. Braun and the paper was that which gained for him the Howard medal for a prize essay on the "Cost, Conditions, and Results of Hospital Relief in London." Founded for the most part by private donors and largely maintained from that source, they are mainly managed by trustees and are independent of the charity commissioners or other body. In the last decade the King's and the Sunday Funds have succeeded in introducing more uniformity into accounts. The paper contained a detailed examination of the statistics and accounts for 1906 of 123 hospitals in Greater London, excluding, as far as possible, expenditure on teaching, on convalescent and nursing homes. The total ordinary expenditure amounted to £999,982, being £227,252 for provisions, £118,006 for surgery and dispensary charges, £195,966 domestic expenses, £96,792 for rent, rates, taxes, repairs, etc., and £226,995 for salaries, wages, and pensions. The management expenses varied from 1.3 to 26 per cent. of the total, the most economical working being by the very large and the very small hospitals, due, no doubt, on the one hand to the larger scale and on the other to the absence of a paid secretariat. The highest figures are those of the Blackfriars Skin and the Royal Waterloo Hospitals, the lowest the Sydenham Children's and St. John's, Lewisham. In the great hospitals the lowest percentage is St. Bartholomew's (3.2), St. Thomas's (3.3), the London (3.9). The author pleaded for a great improvement in the accounts, and toward that end a separation between in-patient and out-patient accounts and also a uniform system of statistics. The summary of statistics of the 123 hospitals shows 10,947 beds, 8,977 being the average number in daily use; 132,670 in-patients and 1,871,405 out-patients. The income of the hospitals from invested property was £265,089, or 31.3 per cent. of the total ordinary income. The twelve great general hospitals with medical schools derived 52.8 per cent. of their united incomes from investments—the percentage varying from 96 per cent. at St. Bartholomew's and 93.3 at St. Thomas's to 14 at the Royal Free and 10.9 at St. Mary's. The author's investigations clearly show that the work done by the hospitals is very great, but the conclusion to which he points will not be anticipated by many. "So great are the figures of patients treated," he says, "that other feelings are swamped in the realization of the physical degradation implied by them. Add to these patients the 30,000 dealt with by the Metropolitan Asylums Board, the unknown number of infirm and sick dealt with by the Poor Law guardians during the year (on February 10, 1906, there were 13,500 in the Poor Law Infirmaries, on January 1 30,000 were in receipt of outdoor medical relief), the 28,000 London lunatics, and the unknown numbers dealt with by provident and charitable dispensaries and private practitioners—and one is appalled by the misery and disgrace of it all. However noble the work that the hospitals are doing, it is of the order of 'patchwork.' This must be so, or they could not keep their numbers. Other hands than those of the hospitals, and other methods striking at the roots, must be put in play before we shall have a healthy community of which one can be proud."

The Seaside doctors have been exercised of late as to the value of sea bathing compared with a resort to inland brine springs and incidentally as to the effects of sea water and sea air in various conditions. The question started afresh last month and many of us have talked about it since. It began with a paper by Dr. Brodribb of Hastings on "The Therapeutic Uses of Sea Water," read at the Balneological and Climatological Society. He was inclined to blame our South Coast authorities for neglect of their resources. He dwelt on the various modes of applying sea water—baths, douches, sprays, and so on, as well as on the numerous conditions in which the remedy was useful.

Dr. Street held that the value of brine baths at the inland spas had been long admitted and sea baths were certainly of equal use, though the explanation of the action was in neither understood.

Dr. Gurney pointed out that in sea bathing the mechanical stimulation of the skin by the salt was increased by the impact of the waves and this must, he thought, render it in many cases more effectual than the use of inland brine baths.

Dr. Buckley said we could not contend that sea water was more powerful on account of the excess of solid ingredients, for we had no definite knowledge as to what were the constituents to which mineral waters owed their remedial virtues. One might have anticipated further consideration of persons and temperature as well as of variety of atmospheric conditions at a society which professes to be climatological.

Following this discussion was a paper dealing with rheumatic affections, which seems specially suited for the society. But the paper was not on spa or climate effects, but a plan of rather active treatment by counterirritation applied to the spine. It was by Dr. W. J. Middleton of Bournemouth, who reported that he had treated with more or less success 27 cases of polyarticular rheumatoid disease (besides two of hysteria and three of paralysis) by blisters in the neighborhood of the cervical and lumbar enlargements of the spinal cord.

He thought the good effect might be due to some extent to the elimination of germs in the discharge and not merely to the action on the nervous system. Dr. Luff of London had employed blistering the spine in various joint diseases, but confessed that the results had not satisfied him. Dr. Armstrong of Buxton had employed electric cautery to the sides of the cervical enlargements when the joints of the superior extremities were most affected and the lumbar enlargement when the inferior were chiefly suffering. He took care not to make lesions of the skin. The treatment was not a specific for arthritis, but he was able to report improvement in many cases. Dr Buckley of Buxton had tried blisters and other counterirritants in these cases and preferred Paquelin's cautery. He felt sure it relieved pain, but it was not curative nor did he expect it to be, for he believed the disease was bacterial.

Dr. Mantle of Harrogate did not think the treatment any advance. Dr. Llewellyn Jones of Bath looked upon the method with favor. We have heard something of this plan in London lately and there are some who appear to think it rather novel.

The death of Dr. Alex. Patterson, late surgeon to the Western Infirmary, Glasgow, removes one of the

most distinguished operators of that city. He retired some time since, but for many years his position was one of the highest. He graduated at the university in 1854, took the F.R.C.S. in 1860, and in a few years established a position almost unrivaled. He anticipated the fresh air treatment, as from an early period he insisted on open windows in the wards night and day. He adopted Lister's views from the beginning and carried them out most strictly. He was the first surgeon to cut down and extract a stone from the kidney. His colleagues reposed the greatest confidence in his surgical judgment, as well as his remarkable operative skill, and quote him as a man of the most upright character.
